Version d330225

This PDF is the concatenation of four different files:

1. **EvAM-Tools: additional technical documentation:** Additional documentation about EvAM-Tools. These include technical details (CPMs, error models, predicting genotype frequencies, generation of random evam models), and a FAQ.
2. **EvAM-Tools: examples:** Commented examples, with both real and simulated data, that illustrate the use and utility of EvAM-Tools.
3. **Package evamtools help:** The help files for the evamtools R package, collated as a single pdf.
4. **Using OncoSimulR to get accessible genotypes and transition matrices:** How we can use OncoSimulR to get accessible genotypes and transition matrices for CBN (and MCCBN), OT, HESBCN, and OncoBN; this provides additional testing and makes the fitness models explicit.

1 Introduction

This document provides additional documentation about EvAM-Tools and the methods included in it; some of the sections complement the Shiny web GUI application help, others apply to the package, or to both. You can run the web app from <https://iib.uam.es/evamtools/> or download a Docker image from <https://hub.docker.com/r/rdiaz02/evamshiny>; to run the R package download a Docker image from <https://hub.docker.com/r/rdiaz02/evamrstudio>. An additional file, `evamtools_examples.pdf`, from https://rdiaz02.github.io/EvAM-Tools/pdfs/evamtools_examples.pdf, includes commented examples, with both real and simulated data, that illustrate the use and utility of EvAM-Tools.

2 Cancer Progression Models included in EvAM-Tool: details

2.1 Cancer Progression Models and cross-sectional data: overview and type of input data

In cross-sectional data a single sample is obtained from each subject or patient. That single sample represents the "observed genotype" of, for example, the tumor of that patient. Genotype can refer to single point mutations, insertions, deletions, or any other genetic modification; in fact, these models have been used to analyze point mutations, gains and losses of CGH regions, SNP alterations, pathway alteration data, etc: the granularity of the data and level of analysis depend on the question addressed, and is not inherent to the models. As is often done by Cancer Progression Models (CPM) software, we think of the cross-sectional data as being stored in a matrix, where rows are patients or subjects, and columns are genes/CGH regions/SNPs/pathways/etc; the data is a 1 if the event (or alteration or mutation) was observed and 0 if it was not.

We have used expressions such as "genotype", "mutation" and other genetic- and genomic-related terms, but nothing prevents CPMs from being used with non-genetic, non-genomic data, and thus our preference for the expression "event accumulation models". The key features that the data must have to be properly analyzed with these methods are: a) that events or alterations are (or can be reasonably assumed to be) gained one by one; b) that once gained, they are not lost (e.g., there is no back mutation); c) that we can consider the different subjects/patients in the cross-sectional data as replicate evolutionary experiments or runs where all individuals are under the same constraints (e.g., genetic constraints if we are dealing with mutations); see further details below ([section 2.2, "Cancer Progression Models \(CPMs\): assumptions"](#)).

Cancer progression models (CPMs) or, more generally, event accumulation models, use these cross-sectional data to try to infer restrictions in the order of accumulation of events; for example, that a mutation on gene B is always preceded by a mutation in gene A (maybe because mutating B when A is not mutated results in a lethal state for that cell). Inferring restrictions, in the sense just explained (B only if A), is what CBN, OT, OncoBN, and H-ESBCN do. Other cancer progression models, such as MHN, instead of modeling deterministic restrictions, model promoting/inhibiting interactions between genes, for example that having a mutation in gene A makes it very likely to gain a mutation in gene B.

2.2 Cancer Progression Models (CPMs): assumptions

CPMs assume that the observations in the cross-sectional data set are independent realizations of evolutionary processes where the same constraints hold for all tumors; therefore, a cross-sectional data set is considered a set of replicate evolutionary experiments where all individuals are under the same (genetic) constraints (Gerstung *et al.*, 2011; Beerewinkel *et al.*, 2015, 2016;

Diaz-Uriarte and Vasallo, 2019). The objective of CPMs is to infer these constraints. CPMs assume that events are gained one by one (no simultaneous acquisition of events) and that there is no back mutation so that once gained an event is not lost; CPMs also assume that the events that drive the process (driver genes if we are thinking about cancer) are known and present in the data set. Finally, CPMs assume that all subjects start the evolutionary process without any of the studied events (i.e., all subjects start the process with 0s in the matrix of subjects by alterations). If we think about cancer, this means that “CPMs assume that all tumors start cancer progression without any of the mutations considered in the study (the above matrix of subjects by driver alterations), but other mutations could be present that have caused the initial tumor growth” (Diaz-Uriarte and Vasallo, 2019); these other additional mutations that lead to the initiation of the process are absorbed in the root node from which cancer starts (Attolini *et al.*, 2010).

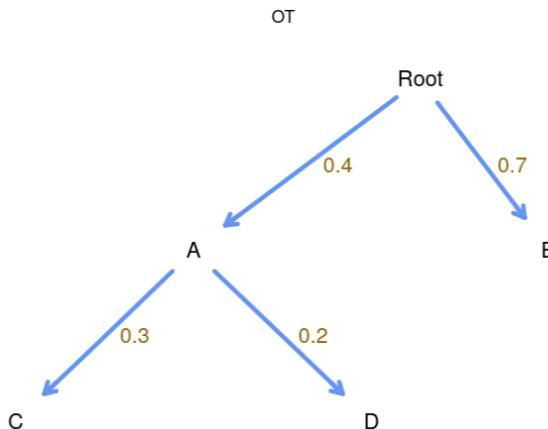

2.3 Cancer Progression Models (CPMs): details

2.3.1 Oncogenetic Trees (OT)

OTs are among the earliest formal models of accumulation of mutations in cancer. They were originally described in Desper *et al.* (1999) (see also Simon *et al.*, 2000; Radmacher *et al.*, 2001); additional references include Szabo and Boucher (2008); Szabo and Pappas (2022); Szabo and Boucher (2002). With OTs, restrictions in the accumulation of mutations (or events) are represented as a tree. Hence, a parent node can have many children, but children have a single parent: therefore, an event can only directly depend on another event. OTs are untimed models (in contrast to, for example CBN, explained in section 2.3.3): weights along edges (the π_{xy} we will use below) can be directly interpreted as probabilities of transition along the edges by the time of observation (Szabo and Boucher, 2008, p. 5). In other words, edge weights represent conditional probabilities of observing a given mutation, when the sample is taken, given the parents are observed.

As explained in (Szabo and Boucher, 2008, Definition 1, p. 4): “A pure untimed oncogenetic tree is a tree T with a probability $\pi(e)$ attached to each edge e . This tree generates observations on mutation presence/absence the following way: each edge e is independently retained with probability $\pi(e)$; the set of vertices that are still reachable from M_0 [the root of the tree, representing no alterations] gives the set of the observed genetic alterations.”

To give an example, suppose a tree as follows:

In this tree, events (mutations) A and B can be acquired independently, and depend on no one (Root is M_0 in the notation of Szabo and Boucher, 2008). C and D depend on A (and are independent of each other, conditional on A). The parameters of the model, shown in brown,

are:

- Probability of acquiring A , $\pi_{0A} = 0.4$; π_{0A} is the notation in Szabo and Boucher, 2008, and is the *weight* along the edge from M_0 to A .
- Probability of acquiring B , $\pi_{0B} = 0.7$.
- Probability of acquiring C , given A has already been acquired, $\pi_{AC} = 0.3$ (again, π_{AC} is the *weight* along the edge from A to C).
- Probability of acquiring D , given A has already been acquired, $\pi_{AD} = 0.2$.

According to the above model, the tumor develops as follows: starting from Root (or M_0), the tumor can gain A and B , and these are independent events. If A is gained, then the tumor can gain C and D , and these two are again independent events (once A has been gained). Therefore, the probabilities of the different genotypes or states of the tumor at the time of sampling are:

- Only Root or M_0 , i.e., no events gained: $(1 - \pi_{0A})(1 - \pi_{0B})$.
- Only A occurs (i.e., genotype A): $\pi_{0A}(1 - \pi_{0B})(1 - \pi_{AC})(1 - \pi_{AD})$.
- Only B occurs (i.e., we observe genotype B): $\pi_{0B}(1 - \pi_{0A})$.
- Both A and B (but no C or D), genotype AB : $\pi_{0A}\pi_{0B}(1 - \pi_{AC})(1 - \pi_{AD})$.
- A and C , genotype AC : $\pi_{0A}(1 - \pi_{0B})\pi_{AC}(1 - \pi_{AD})$.
- Both B and C but no A , genotype BC : 0 (as A needs to occur before C can occur).
- ...

The above describes the ideal scenario, without errors. OT includes a model for errors from different sources: deviations from the model (i.e., events that do not respect the pure untimed model above) and observational (e.g., genotyping) errors. Together, these two types of error cause false positive and false negative observational errors (ϵ_+ , ϵ_-). These error rates are estimated by the OT algorithm and are incorporated in the computation of the predicted frequencies of genotypes according to OT (see details in “[CPMs: Error models](#)”, section 2.3.6).

When using OT, as explained in Szabo and Boucher (p. 5 2008), the main objective is reconstructing the topology of the tree; the estimation of the edge probabilities (the weights or π_{xy}) and the error rates (ϵ_+ , ϵ_-) is of secondary importance. As detailed in Szabo and Boucher (2008, p. 5), the estimation of the topology uses an “(...) algorithm [that] takes a greedy bottom-up approach: it assigns the parent of each node by finding the maximum-weight in-edge starting from the leaves.” and that provides a computationally fast way of inferring the tree. The full algorithm for topology reconstruction is provided in Szabo and Boucher (2008, Section 3 and Fig. 2) (the algorithm is also provided in Figure 2 of file `ot.pdf`, part of the documentation of Szabo and Pappas, 2022); estimation of the weights is detailed in Szabo and Boucher (2008, p. 13). Sufficient conditions for the reconstruction of the true tree when there are false positive and false negative errors are given in Szabo and Boucher (2002) and sample size requirements in Szabo and Boucher (2008, p. 8)(see also Desper *et al.*, 1999).

2.3.2 OncoBN

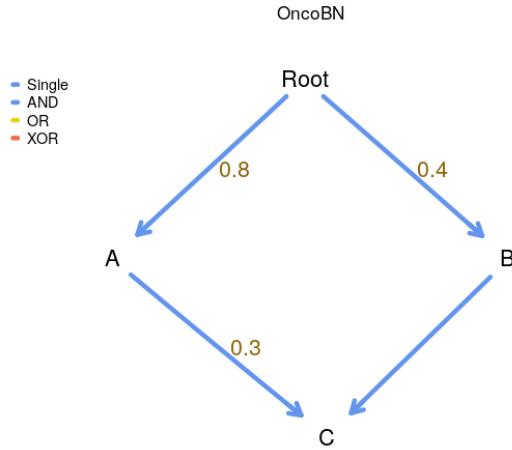

OncoBN, described in Nicol *et al.* (2021), is similar to OT in the sense of being an untimed oncogenetic model but, in contrast to OT, a node can have multiple parents. When there are multiple parents the relationships and models can be of two different kinds:

- disjunctive (OR relationship): the DBN, Disjunctive Bayesian Network model;
- conjunctive (AND relationship): the CBN, Conjunctive Bayesian Network model.

A given OncoBN be either a DBN or a CBN, but not both: it can have conjunctive or disjunctive relationships, but not both. (And note that the CBN models fitted by OncoBN are untimed, and thus the parameters do not have the same interpretation as the parameters of the CBN models discussed below, “*Conjunctive Bayesian Networks (CBN)*” (section 2.3.3)).

As explained in Nicol *et al.* (2021, p. 2), a key difference between the conjunctive (AND) and the disjunctive (OR) model is that under the conjunctive model all parent alterations that constitute the AND relationship must be present in a cell for the child mutation to occur; the disjunctive model, in contrast, allows child event to occur when just one of the parent events has taken place. According to the authors, this might make the model better for modeling intra-tumor heterogeneity.

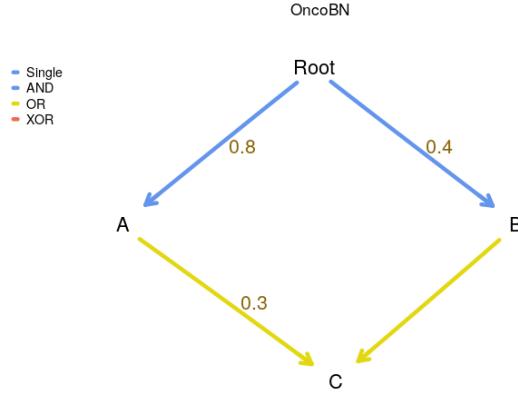

The following DAG shows a conjunctive model fitted with OncoBN:

Note that the value of 0.3 is the value of the parameter θ_C : this is the conditional probability of C given its ancestors. (So, in contrast to OT, but similar to CBN and H-ESBCN, the parameters are not of edges, but of events). The values of θ are: $\theta_A = 0.8$, $\theta_B = 0.4$, $\theta_C = 0.3$. According to the OncoBN model the probabilities of some genotypes are:

- Only Root (i.e., only genotypes without any mutation, or “WT”): $(1 - \theta_A)(1 - \theta_B)$.
- Only A , i.e., genotype A : $\theta_A(1 - \theta_B)$.
- A and C , genotype AC : 0, since acquiring C requires also B .
- A and B (but not C), genotype AB : $\theta_A\theta_B(1 - \theta_C)$.
- All of A , B , C , genotype ABC : $\theta_A\theta_B\theta_C$.
- Only C : 0, since neither A nor B have occurred.

The next DAG is identical, except the model is a disjunctive one (notice the edges are OR edges):

Now, θ_C is the probability of C occurring if at least one of its ancestors has occurred. Therefore, we have the following probabilities of some of the genotypes, where those that differ from the conjunctive case have been marked in bold with an initial asterisk:

- Only Root (i.e., only genotypes without any mutation, or “WT”) : $(1 - \theta_A)(1 - \theta_B)$.
- * **Only A:** $\theta_A(1 - \theta_B)(1 - \theta_C)$.
- * **A and C, genotype AC:** $\theta_A(1 - \theta_B)\theta_C$.
- **A and B (but not C), genotype AB:** $\theta_A\theta_B(1 - \theta_C)$.
- All of A, B, C , genotype ABC : $\theta_A\theta_B\theta_C$.
- Only C : 0, since neither A nor B have occurred.

The above represent the probabilities in a model without errors. OncoBN includes an error model, the “spontaneous activation model” where there is a non-zero probability of observing child events when restrictions in the DAG are not satisfied. The rate of spontaneous activation is part of the estimation procedure, and is included in the computed probabilities of the different genotypes (see details in [section 2.3.6, “CPMs: Error models”](#)). For example, under the disjunctive model above, the probability of observing genotype C would be $(1 - \theta_A)(1 - \theta_B)\epsilon$, where ϵ is the spontaneous activation probability, which is set as the same for all events (Nicol *et al.*, 2021, p. 5)). (Figure 1 of Nicol *et al.*, 2021 provides another example of the role of ϵ in computing predicted probabilities).

Structure learning can be conducted using an exact procedure that uses dynamic programming, recommended when there are less than 30 events; for larger problems, approximate structure learning using genetic programming is available.

2.3.3 Conjunctive Bayesian Networks (CBN)

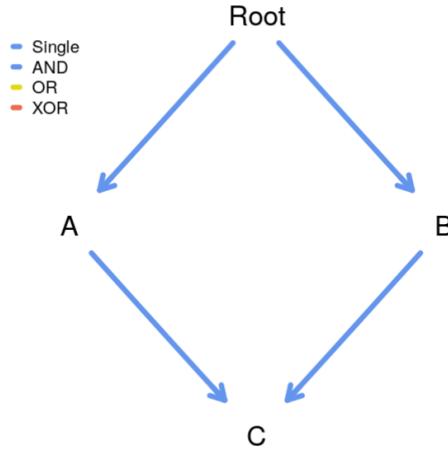

In terms of the representation of the restrictions, CBN, like OncoBN, generalizes the tree-based restriction of OT to a directed acyclic graph (DAG): a node can have multiple parents. A node with multiple parents means that all of the parents have to be present (all of the parent events must have occurred) for the children to appear; therefore, relationships are conjunctive—AND relationships between the parents (recall OncoBN can model AND and OR relationships). CBN also differs from OT and OncoBM because the CBN model is a timed model: the λ s, the parameters of the models, are the rates of the exponentially distributed

times to fixation of an event given that all parents of that event have been observed (i.e., given that the event restrictions, as specified in the DAG, are satisfied: Montazeri *et al.*, 2016, p. i729; Gerstung *et al.*, 2009, section 2.2).

Specifically, T_i , the waiting time for event i to occur, is an exponentially distributed random variable with parameter λ_i conditioned on all the parent mutations, $\text{pa}(i)$, having occurred (Gerstung *et al.*, 2009); thus, T_i is defined recursively as (Gerstung *et al.*, 2009; Hosseini *et al.*, 2019):

$$T_i \sim \text{Exp}(\lambda_i) + \max_{j \in \text{pa}(i)} T_j \quad (1)$$

To give an example, suppose a DAG as follows:

Then, the time to fixation of the three mutations (not genotypes) are:

- $T_A \sim \text{Exp}(\lambda_A)$
- $T_B \sim \text{Exp}(\lambda_B)$
- $T_C \sim \text{Exp}(\lambda_C) + \max(T_A, T_B)$

and we will not observe C unless both A and B have occurred.

The λ parameters of the CBN model define the transition rate matrix between genotypes (see also Montazeri *et al.*, 2016). For the example above we have:

- Rate from WT to genotype with A mutated: λ_A .
- Rate from WT to genotype with B mutated: λ_B .
- Rate from genotype with A mutated to genotype with both A and B mutated: λ_B .
- Rate from genotype with B mutated to genotype with both A and B mutated: λ_A .
- Rate from genotype with A and B mutated to genotype with A, B, C mutated: λ_C .

In other words, this is the transition rate matrix, where only genotypes that can appear are shown (i.e., genotypes C , AC , and BC are not shown):

$$Q = \begin{matrix} & \begin{matrix} WT & A & B & AB & ABC \end{matrix} \\ \begin{matrix} WT \\ A \\ B \\ AB \\ ABC \end{matrix} & \begin{pmatrix} -(\lambda_A + \lambda_B) & \lambda_A & \lambda_B & 0 & 0 \\ 0 & -\lambda_B & 0 & \lambda_B & 0 \\ 0 & 0 & -\lambda_A & -\lambda_A & 0 \\ 0 & 0 & 0 & -\lambda_C & \lambda_C \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \end{matrix} \quad (2)$$

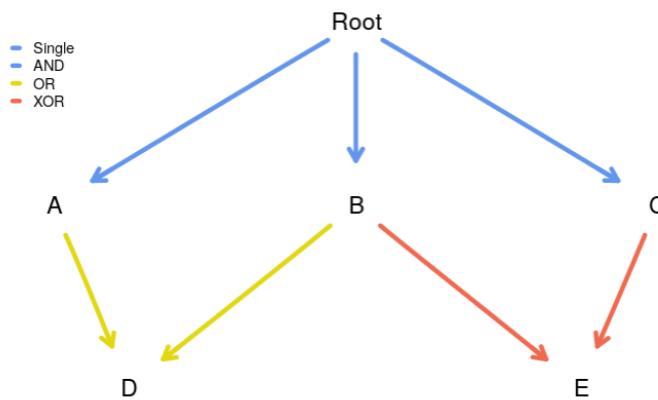

For parameter estimation, and since the observation times of the different individuals are unknown, it is assumed that observation time is exponentially distributed with parameter 1 (the probabilities of observing the different events are invariant under rescalings of the λ_i and the λ_s , the rate of the time to observation — Gerstung *et al.*, 2009).

H-CBN, described in Gerstung *et al.* (2009, 2011) uses simulated annealing with a nested expectation-maximization (EM) algorithm for estimation; MC-CBN, described in Montazeri *et al.* (2016), uses a Monte-Carlo EM algorithm. In EvAM-Tools we include both H-CBN as well as MC-CBN. H-CBN and MC-CBN also differ in their error models: in H-CBN the λ s describe the true underlying model that produces the true, hidden genotypes, but the observed genotypes might differ from the true ones because of observation error; in MC-CBN the model is a mixture between the CBN model and a noise component model (see details in “[CPMs: Error models](#)”, section 2.3.6). The error models are, of course, part of the fitting algorithm.

2.3.4 Hidden Extended Suppes-Bayes Causal Networks (H-ESBCN)

H-ESBCN (Hidden Extended Suppes-Bayes Causal Networks), described in Angaroni *et al.* (2021) (and used by its authors as part of Progression Models of Cancer Evolution, PMCE), is similar to CBN in that it is a timed model, where parameters of the model, the λ s are the rates of the exponentially distributed times to fixation of an event given that the parents of that event have been observed. In contrast to CBN, the dependency relationships are not limited to AND, and they can include OR and XOR. In contrast to OncoBN with respect to dependencies, H-ESBCN adds XOR relationships, but H-ESBCN allows the very same model to include AND, OR, and XOR relationships; the fitting algorithm includes automatic inference of logical formulas for these three different patterns, AND, OR, XOR.

To give an example, suppose the following DAG (we only show XOR and OR relationships, since we have already shown AND relationships in examples above, and there is nothing new with AND relationships); this example is discussed, in another context, in “[An example with OR and XOR](#)” (section 7.4):

According to this DAG

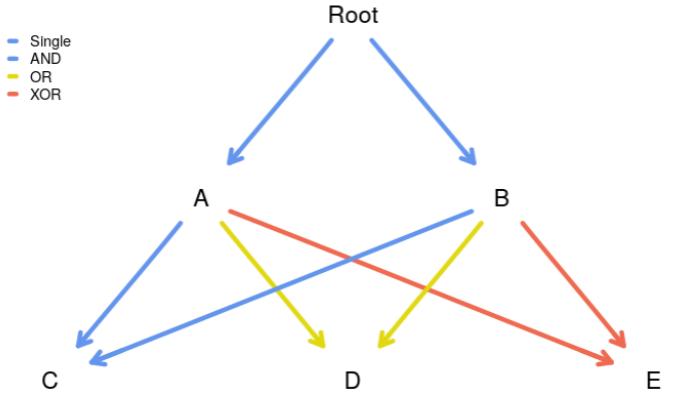

- A, B, C depend on none, and their rates are, respectively, $\lambda_A, \lambda_B, \lambda_C$.
- D depends, with an OR, on both A and B : the rate of fixation of D given at least one of A or B have occurred is λ_D . Thus, we can observe genotypes AD, BD, ABD .
- E depends, with an XOR, on B and C : the rate of occurrence of E given exactly one of B XOR C has occurred is λ_E . Thus, E can only be observed in genotypes that show

B XOR C , such as genotypes BE , CE , ABE , ACE ; genotypes BCE or $ABCE$, in contrast, are not allowed because those genotypes have both B and C mutated.

The transition rate matrix between genotypes is shown below, where rows are origin, column destination (i.e., entries of Q_{xy} are the transition rates from x to y):

	WT	A	B	C	AB	AC	AD	BC	BD	BE	CE	ABC	ABD	ABE	ACD	ACE	BCD	BDE	ABCD	ABDE	ACDE	
WT		λ_A	λ_B	λ_C																		
A					λ_B	λ_C	λ_D															
B					λ_A			λ_C	λ_D	λ_E												
C						λ_A		λ_B														
AB								λ_C	λ_D	λ_E												
AC									λ_B				λ_C	λ_D	λ_E							
AD										λ_B				λ_D	λ_E							
BC										λ_A				λ_B								
BD											λ_A				λ_C	λ_D	λ_E					
BE											λ_A				λ_D							
CE												λ_A				λ_C	λ_D	λ_E				
ABC													λ_A				λ_D					
ABD														λ_B			λ_C					
ABE															λ_B			λ_D				
ACD																λ_B			λ_D			
ACE																	λ_B			λ_E		
BCD																		λ_B			λ_E	
BDE																		λ_A				
ABCD																		λ_A				
ABDE																		λ_A				
ACDE																		λ_A				

Note that it is possible to have two (or more) parents to have dependents with different relationships. This, for example, is one of the pre-loaded DAGs in EvAM-Tools:

The error model is similar to the one of CBN “*Conjunctive Bayesian Networks (CBN)*” (section 2.3.3), as described in Gerstung *et al.* (2009); see also “*CPMs: Error models*” (section 2.3.6). The fitting algorithm is described in (Sections 2.1, 2.2 Angaroni *et al.*, 2021); as for other methods, its main focus is inferring the structure of the DAG, in this case the maximum a posteriori in the framework of Suppe’s probabilistic causation; a key feature of the algorithm is the attempt to automatically detect the correct logical formula (AND, OR, XOR). The structure searching algorithm uses MCMC from a randomly initialized structure which is modified according to different possible moves. To avoid fitting unneeded logic formulas, the structure learning algorithm includes regularization, which can be chosen by the user to be AIC or BIC. Estimation of the λ s (and error rate) for a fixed DAG structure is done using an EM algorithm.

2.3.5 Mutual Hazard networks (MHN)

All of the methods described above share a model of deterministic dependencies for the accumulation of events (or mutations) (Schill *et al.*, 2020): an event (a mutation) can only occur if its dependencies are satisfied (though note that both OT and OncoBN, as well as MB-CBN allow for error deviations from this requirement — see “[CPMs: Error models](#)”, section 2.3.6).

In contrast to the previous methods, with MHN (Schill *et al.*, 2020) dependencies are not deterministic and events can make other events more likely (promoting influence) or less likely (inhibiting influence). The rate of occurrence of events is modeled by a spontaneous rate of fixation and a multiplicative effect that each of these events can have on other events via pairwise interactions; these pairwise interactions are what allow MHN to model both promoting and inhibiting dependencies.

In more detail, the Markov process that governs the transition from a genotype \mathbf{x} to a genotype with mutation i added to genotype \mathbf{x} is specified by (Schill *et al.*, 2020, eq. 2):

$$Q_{\mathbf{x}_{+i}, \mathbf{x}} = \Theta_{ii} \prod_{x_j=1} \Theta_{ij} \quad (3)$$

where x_j is 1 if gene j is already mutated in genotype \mathbf{x} , and $Q_{y,x}$ is the transition rate from x to y (we are using the notation in Schill *et al.*, 2020, where transition rate matrices are transposed relative to the notation in Montazeri *et al.*, 2016 that we have used when describing CBN and H-ESBCN). Θ_{ii} is the baseline hazard or the rate of i before any other events; Θ_{ij} is the multiplicative effect of event j on the rate of event i . Therefore, equation 3

shows the transition rate as the product of the baseline hazard times the multiplicative effects of all the other mutated genes or events, j , on i .

To give a specific example, suppose the Θ matrix for a three-gene model¹ is:

$$\Theta = \begin{bmatrix} \Theta_{11} & \Theta_{12} & \Theta_{13} \\ \Theta_{21} & \Theta_{22} & \Theta_{23} \\ \Theta_{31} & \Theta_{32} & \Theta_{33} \end{bmatrix} \quad (4)$$

The following are the transition rates for some transitions:

- From WT to the genotype with the first event or gene: Θ_{11} .
- From the genotype with the first event to the genotype with the first and the second events: $\Theta_{22}\Theta_{21}$.
- From the genotype with the first event and second events to the genotype with the third event: $\Theta_{33}(\Theta_{31}\Theta_{32})$.

Note that in EvAM-Tools we show the log- Θ matrix, the matrix of θ_{ij} , where $\Theta_{ij} = e^{\theta_{ij}}$, because this makes it immediate to identify the inhibiting relationships as those with a negative sign, and it symmetrizes the effects around 0.

As can be seen, the relationships between events are inhibiting (event j inhibits event i if $\Theta_{ij} < 1$ or, equivalently, $\theta_{ij} < 0$) or promoting ($\Theta_{ij} > 1$ or, equivalently, $\theta_{ij} > 0$), but there are no deterministic restrictions (although MHN can be seen as a stochastic approximation to the deterministic dependencies of CBN: see the supplementary material of Schill *et al.*, 2020).

To fit the model, because observation time is unknown, and as is done by Gerstung *et al.* (2009), the authors assume that observation times are exponentially distributed with parameter 1. To prevent overfitting, the model fitting procedure maximizes the likelihood of the data minus an L1 penalty to try to avoid many interacting events (i.e., to promote sparsity of the fitted models): it uses a tuning parameter, λ^2 that multiplies the sum of the absolute values of the off-diagonal entries of the log Θ matrix (Schill *et al.*, 2020, eq. 6). The default value of λ is 1/number of rows of the data set. The authors provide an efficient implementation of their method that uses a Quasi-Newton algorithm.

2.3.6 CPMs: Error models

We have mentioned error models when describing each procedure. We put together those details here, to allow for easier understanding of the similarities and differences between methods. (Methods are not ordered as above but, rather, by increasing complexity of the error model).

MHN There is no explicit error model (the simulation process described in p. 244 of Schill *et al.*, 2020 uses a scheme as the one in CBN, Gerstung *et al.*, 2009, explained below, but that is not part of the MHN model itself).

CBN In H-CBN the λ s describe the true underlying model that produces the true, hidden genotypes, but the observed genotypes might differ from the true ones because of observation error, for instance genotyping error (Gerstung *et al.*, 2009, p. 2810). The observation error is a Bernoulli process, in which a mutation is falsely observed with probability ϵ , which is assumed to be the same and independent across all sites (see also Sakoparnig and Beerenwinkel, 2012, p. 2319); in other words, for all events of all

¹As a different example, see the set of transitions for a four-gene example in Schill *et al.*, 2020, Fig. 2.

²This λ is different from the λ s of CBN and H-ESBCN

subjects in the sample, if the true observation is a 0, it has a probability of being observed as a 1 of ϵ , and similarly for an observation that is truly a 0.

H-ESBCN As for CBN (Angaroni *et al.*, 2021, p. 756).

MC-CBN With MC-CBN the model is a mixture between the CBN model and a noise component model (Montazeri *et al.*, 2016, p. i730-i731). The simulations in <https://github.com/cbg-ethz/MC-CBN>, however, use a procedure where observations are generated from an underlying poset with a given set of lambdas, and symmetric error is then added (see the functions `mccbn:::random_poset` and `mccbn:::random_posets`), as for CBN above.

OncoBN The model includes a DBN (disjunctive) or CBN (conjunctive) model, as given by a DAG and a set of θ s, and a “spontaneous activation model” (Nicol *et al.*, 2021, p. 3-4). The “spontaneous activation model”, with parameter ϵ , represents deviations from the model and allows child mutations to appear even if the parents in the DAG have not been mutated (i.e., even if the restrictions encoded in the DAG are not satisfied). (This ϵ , therefore, has a different meaning from the ϵ of CBN and H-ESBCN).

OT There are two sources of deviations from the OT model: a) those that result from observational (or genotyping) errors, that can lead to both false positive and false negative observational errors; b) events occurring that do not respect the OT model (Szabo and Boucher, 2002, 2008). The second would be the same as the “spontaneous activation” in OncoBN.

The `oncotree.fit` function in the `Oncotree` package returns a `eps` component with the estimated false positive, `epos` (ϵ_+), and false negative, `eneg` (ϵ_-), error rates. But these are the result of combining the two sources of error (Szabo and Boucher, 2008): observation errors and true deviations from the model. So observation error is reflected in both `eneg` (ϵ_-), and `epos` (ϵ_+), whereas true deviations from the model are only reflected in `epos` (ϵ_+). In other words, the false negatives, as measured by the estimated `eneg`, are due purely to observation error. But the `epos` are not equivalent to the ϵ of OncoBN: `epos` includes both observation error (false positives) and true mutations that occur without respecting the restrictions of the OT DAG (tree).

So, when obtaining predicted frequencies under the model, for CBN, H-ESBCN, and MHN, we assume perfect compliance with the model; symmetric noise (e.g., genotyping noise) is added only when obtaining finite samples from the model. For OT and OncoBN the predicted frequencies from the model already include deviations from the fitted model.

2.3.7 CPMs: output

All methods provide directly, as output, estimates of the key constituents of their models, in particular:

OT Tree of restrictions, edge weights (π s), errors (ϵ_+, ϵ_-).

OncoBN DAG of restrictions, event θ , spontaneous activation probability or error (ϵ).
(The type of model, conjunctive or disjunctive, is not estimated, but set by the user).

CBN DAG of restrictions, λ s, error rate.

H-ESBCN DAG of restrictions, including type of restriction (AND, OR, XOR), λ s, error rate.

MHN Θ matrix (or its equivalent θ or $\log\Theta$ matrices).

In addition, directly derived predictions, such as **predicted probabilities of genotypes** are provided by the original code/implementation (e.g., for OT, OncoBN, MHN) or can be obtained for CBN and H-ESBCN from the transition rate matrices (see details in “*Predicted genotype frequencies*”, section 3). From the predicted probabilities of genotypes we can obtain **finite sampled genotype counts**, as explained in “*Error models and obtaining finite samples (or sampled genotype counts)*” (section 5.2).

Transition rate matrices themselves are not part of the immediate output of any of the methods (except MHN³) but, as explained in “*Predicted genotype frequencies*” (section 3), can be obtained from the DAG and the λ s, as we do in EvAM-Tools; we have already seen examples of the transition rate matrices for all of CBN (“*Conjunctive Bayesian Networks (CBN)*”, section 2.3.3), H-ESBCN (“*Hidden Extended Suppes-Bayes Causal Networks (H-ESBCN)*”, section 2.3.4), and MHN (“*Mutual Hazard networks (MHN)*”, section 2.3.5). From the transition rate matrices it is also possible to obtain the **probabilities of evolutionary paths** and the **transition probabilities** (for instance, using competing exponentials; see references and details in section 4, “*Probabilities of evolutionary paths and transition probabilities*”).

All of this output is available from EvAM-Tools, and the web app shows most of them using both figures and tables. (Probabilities of evolutionary paths, even if asked to be computed, are not explicitly available from the web app, as they can be unwieldy to display; they are provided in the output one can download and are, of course, implicit from the transition probabilities between genotypes, and transition probabilities are displayed in the web app.)

2.3.8 CPMs: summary

The following table provides a summary of the main features of each method.

Method	Timed/ untimed	Number and type of de- pendencies	Restrictions	Representation and out- put
OT	Untimed	Single	Deterministic	Tree with edge weights (π_s)
OncoBN	Untimed	AND (CBN version), OR (DBN version); but a given model can only contain either AND xor OR, not both	Deterministic	DAG with event thetas (θ_s)
CBN	Timed	AND	Deterministic	DAG with event rates (λ_s)
H-ESBCN	Timed	AND, OR, XOR	Deterministic	DAG with event rates (λ_s)
MHN	Timed	Promoting and inhibit- ing (but only pairwise interactions)	Stochastic dependencies	Θ matrix (diagonal en- tries: baseline haz- ards; off-diagonal: mul- tiplicative effects).

³ And we saw an example in “*Mutual Hazard networks (MHN)*” (section 2.3.5)

3 Predicted genotype frequencies

3.1 Predicted genotype frequencies for CBN, MCCBN, MHN, H-ESBCN

Briefly, for CBN, MCCBN, MHN, and H-ESBCN, the transition rate matrix describes the true process that generates genotypes and this matrix can be obtained from the parameters of the model (θ s for MHN, λ s for the rest); we haven seen examples for all these methods in section “[Cancer Progression Models \(CPMs\): details](#)” (section 2.3). Therefore, we can use the transition rate matrix to calculate the predicted probabilities of the different genotypes using standard results from continuous-time Markov Chains. In all cases here, we assume that the time of observation is exponentially distributed with rate 1 (as in Gerstung *et al.*, 2009 or Schill *et al.*, 2020)⁴.

In more detail, obtaining the transition rate matrix from the model output is detailed in Montazeri *et al.* (2016) for CBN, and Schill *et al.* (2020) for MHN; for H-ESBCN see [section 7, “H-ESBCN: details and examples of using \$\lambda\$ s and computing transition rate matrices and predicted genotype frequencies”](#).

Once we have obtained the transition rate matrix, the fastest way to obtain the predicted genotype probabilities is using equation 4 in Schill *et al.* (2020):

$$\mathbf{p} = \int_0^\infty dt e^{-t} e^{tQ} \mathbf{p}_0 = [I - Q]^{-1} \mathbf{p}_0 \quad (5)$$

where \mathbf{p}_0 is the initial distribution (i.e., 1 for WT and 0 for the rest of the genotypes), t is the time of observation (again, assumed to be exponentially distributed with parameter 1), and Q is the transition rate matrix (beware: written here, as in Schill *et al.*, 2020, with Q_{ij} meaning the transition rate from j to i , in contrast to our expressions for transition rate matrices in equation 2 or the transition rate matrix in section 2.3.4). This is implemented in the non-exported function `probs_from_trm`, and follows also what is done in the original `Generate.pTh` from Schill *et al.* (2020). `probs_from_trm` is called from function `evam`. Instead of using that expression, we can sample from the continuous-time Markov Chain using standard procedures (e.g., ch. 5 in Wilkinson, 2019 or Algorithm 1 in Gotovos *et al.*, 2021). Sampling is what we do when you call `sample_CPMs` asking for `obs_genotype_transitions` or `state_counts` to be returned (and this sampling is implemented in the non-exported function `population_sample_from_trm`, and called, as needed, by `sample_CPMs`).

3.2 Predicted genotype frequencies for OT and OncoBN

OT and OncoBN do not return rates of a continuous-time Markov chain, but probabilities of seeing specific alterations at the time of observation. Predicted probabilities of genotypes for OT and OncoBN are obtained using the weights (OT) or θ s (OncoBN), according to the expression for the probability of observing a genotype; these expressions incorporate, when predicting the genotypes, the estimated errors (ϵ_+ , ϵ_- for OT, ϵ for OncoBN; see section “[CPMs: Error models](#)”, section 2.3.6). For example, see section 2.2 in Szabo and Boucher (2008) for OT and Figure 1 and section 2.1 in Nicol *et al.* (2021) for OncoBN. For OT we can use function `distribuition.oncotree` in package `Oncotree` and for OncoBN function `Lik.genotype` from package `OncoBN`⁵.

⁴There is code in `evamtools`, in function `population_sample_from_trm`, to obtain samples at arbitrary collections of times —i.e., not limited to times exponentially distributed with rate 1.

⁵Though for OncoBN we do not use `Lik.genotype` directly, as that would involve making the exact same repeated set of calls for every individual; see the non-exported function `DBN_prob_genotypes` in file `onco.bn-process.R`

For all methods, once we have the predicted probabilities, we can obtain a finite sample and, if we want, add observational (or genotyping) noise; see details in section 5.2, “*Error models and obtaining finite samples (or sampled genotype counts)*”.

4 Probabilities of evolutionary paths and transition probabilities

How to obtain probabilities of evolutionary paths for CBN and OT is detailed in Hosseini *et al.* (2019) and Diaz-Uriarte and Vasallo (2019) (see S4_Text:

<https://doi.org/10.1371/journal.pcbi.1007246.s006>, section 3). For how to obtain transition probabilities see also Diaz-Colunga and Diaz-Uriarte (2021) (specifically section 1 in S1 Appendix: <https://doi.org/10.1371/journal.pcbi.1009055.s001>).

The procedures to obtain transition probabilities and probabilities of evolutionary paths for H-ESBCN and MHN are similar to CBN: in all these methods we obtain probabilities of paths from the transition matrix, which is itself obtained from the transition rate matrix. The procedure with OncoBN is analogous to the one used with OT, both being untimed models (and, in both cases, obtaining probabilities of paths, as discussed in Diaz-Uriarte and Vasallo, 2019 is an abuse of the untimed model).

5 Generating random CPM/EvAM models, obtaining finite samples from them, and error models

5.1 Generating random CPM/EvAM models and sampling from them

We often want to generate data under the model of a CPM. Common use cases are:

- Understand what different models imply about how the cross-sectional data looks like.
- Examine how well a method can recover the true structure when the data fulfills the assumptions of a method. For instance, we would generate data under a particular model and see if the method that implements that model can recover the true structure under different sample sizes.
- Examine how a given method works, and what type of inferences it performs, when data are generated under the model of another method. For example, what is the output from MHN if the data are really coming from an H-ESBCN model?

Addressing the above needs involves:

1. Generating a random model.
2. Obtaining the predicted genotype frequencies from that model (see “*Predicted genotype frequencies*”, section 3).
3. Obtaining a finite sample from the predicted frequencies of that model.
4. Using the data to answer whichever questions we had; for example, analyze the sampled data with another or the same method, plot the genotype frequencies, etc.

We explain each one in turn below, with reference to `evamtools` functions and arguments.

1. Generating a random model.

Function `random_evam` generates random models for OT, OncoBN, CBN, MHN, OncoBN, and H-ESBCN. Details about the arguments of the function are provided in its help page. No specific provision is made for randomly generating from MCCBN, as the way to simulate is similar to CBN (generate a random poset and a random set of lambdas).

2. Obtaining the predicted genotype frequencies from that model.

These are returned as part of the output of `random_evam` (as well as part of the output of `evam`). In all cases, the predicted distribution of genotypes for a model is done assuming perfect compliance with the model; see “*Predicted genotype frequencies*” (section 3).

3. Obtaining a finite sample from the predicted frequencies of that model.

As the output from `random_evam` is the same (except for the data components) to that from `evam` we can pass the model to function `sample_CPMs`.

When obtaining a finite sample, we can add sampling noise to the data. For example, noise due to genotyping errors; the probability of errors is controlled by argument `obs_noise` in the call to `sample_CPMs`.

In more detail, the process involves:

- (a) Obtaining a finite sample without errors from the predicted genotype frequencies.
 - (b) If requested (i.e., if `obs_noise > 0`), flipping a fraction `obs_noise` of the observations (i.e., turning 1s to 0s and 0s to 1s).
4. Using the data to answer whichever questions we had; for example, analyze the sampled data with another or the same method, plot the genotype frequencies, etc.

To make this simpler, function `sample_CPMs` can return the finite sample (with or without observation noise) as a typical cross-sectional data set: a matrix where each row is a “sampled genotype”, in which 0 denotes no alteration and 1 alteration in the gene of the corresponding column. This data matrix can be used directly as input for CPM methods, for instance as argument `x` (the cross-sectional data) to function `evam`.

5.2 Error models and obtaining finite samples (or sampled genotype counts)

When obtaining a finite sample from a model, in all cases except OT, we have always followed the same procedure: we have first generated the predicted genotype frequencies under the model and, if requested, then added observational (e.g., genotyping) noise to the finite samples obtained from the predicted frequencies⁶. Recall that, for OncoBN, the fitted model (and, thus, the predicted frequencies under the model) already include deviations from the model, as measured by ϵ ; see section 2.3.6, “CPMs: Error models” and section 2.3.2, “OncoBN”.

For OT, since `epos` (ϵ_+) reflects both observation error and true deviations from the model, the above procedure is not possible. We need to introduce a difference between sampling from a model specified from scratch, such as a random model returned from function `random_evam`, and sampling from the predictions of a fitted model.

⁶Obtaining a finite sample of size N given a vector of relative frequencies is done in R using the function `sample`

The fitted model for OT, when fitting a true data set, includes both `epos` (ϵ_+) and `eneg` (ϵ_-). Predicted genotype frequencies are obtained using function `Oncotree::distribution.oncotree` with, by default, argument `with.errors = TRUE`, which is what argument `with.errors_dist_ot = TRUE` to `evam` does. Therefore, from a fitted model, the predictions incorporate both false positive and false negative error rates, as estimated by `oncotree.fit`; as explained above, however, these estimated error rates are both the errors from the observational process (genotyping errors, for example) and true deviations from the model. When you later call `sample_CPMs` you can add an `obs_noise` with value larger than 0, but for OT, when sampling from the model fitted to observed data this might not make sense (since `epos` and `eneg` have been used already to produce the predicted genotype frequencies). Thus, if we use `with.errors_dist_ot = TRUE` in the `evam` call and then set `obs_noise = 0` when calling `sample_CPMs`, the observed data we generate should be the same (have the same distribution) as if we had used `Oncotree::generate.data` with `method = "D1"`, `with.errors = TRUE` and `edge.weights = "estimated"`.⁷

When sampling from a model specified from scratch, such as a random model returned from function `random_evam`, we generate the tree (the DAG) with density as given by argument `graph_density` and the weights from uniform distributions with limits given by `ot_oncobn_weight_min` and `ot_oncobn_weight_max`. In addition, we can set a value larger than 0 for `ot_oncobn_epos`. This will be used as the `epos`, but not `eneg`, value of the OT model. When you sample and optionally add noise, with argument `obs_noise` to function `sample_CPMs`, noise is added symmetrically (as for the CBN model —[section 2.3.6, “CPMs: Error models”](#)). Thus, we use a procedure where `ot_oncobn_epos` behaves as OncoBN’s ϵ and `obs_noise` is purely symmetric observational error.

Why this difference? When you use a model fitted to real data, it is sensible to use `Oncotree`’s inferential machinery to estimate the `epos` and `eneg`. If you later want to generate samples, these already include deviations from the model and noise. However, when you simulate a model, there is no data and thus no way to estimate `epos` and `eneg`. Therefore, it is sensible to split errors into two distinct pieces, which is also coherent with what we do with the rest of the methods: deviations from the model, and noise.

6 Random EvAM models and transitive reduction

As of now, the generation of random EvAM models uses transitively reduced graphs (we call `mccbn::random_poset` with argument `trans_reduced = TRUE`). This does not decrease the number of models that can be expressed when using CBN. However, it can limit the range of models when we can mix AND, OR, XOR in the same model. The following examples illustrate how this makes certain models impossible.

- Under the left-most DAG in Fig. 1 we cannot observe genotype BCD.
- Under the center DAG in Fig. 1 we cannot observe genotype ACD.
- Under the right-most DAG, which is the transitive reduction of the above two graphs, we can observe both BCD and ACD.

⁷We can try to divide the `epos` component in a component like OncoBN’s ϵ and another noise component. Then, we would first obtain the predicted distribution via `distribution.oncotree` with the ϵ -like (and with `eneg = 0`), sample, and add noise. If `epos > eneg` we can do this so that the noise added is symmetrical. This is shown in function `dot_noise_gd_3` in `inst/miscell/OT_generate_data_sample_CPMs.R`.

In that same file `inst/miscell/OT_generate_data_sample_CPMs.R` we show that a model obtained from `random_evam` with `ot_oncobn_eps = x` and sampled using `sample_CPMs` with `obs_noise = y` gives predictions with the same distribution as if we had used `Oncotree::generate.data` on that very same `oncotree` object but with `epos = x + y - (1/2) x y` and `eneg = y`.

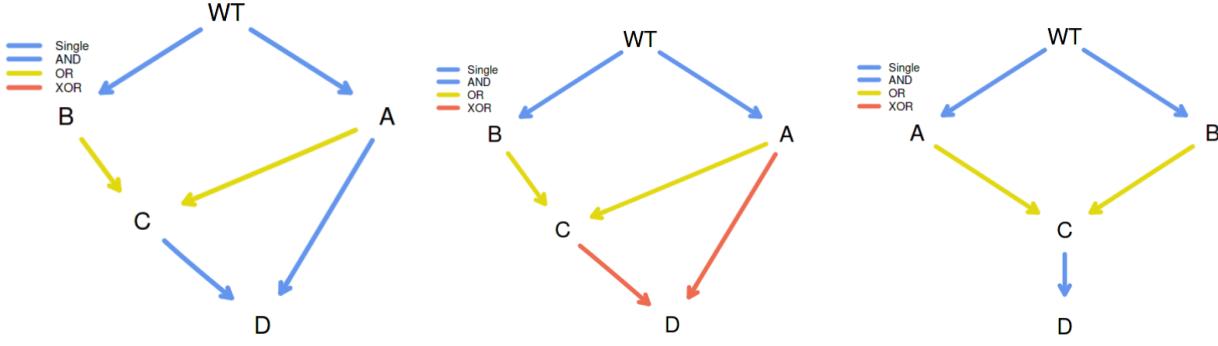

Figure 1: Non-transitively reduced DAG, OR and AND (left), non-transitively reduced DAG, OR and XOR (center), transitively reduced DAG.

Can we imagine biological scenarios where the left-most or center scenarios in Fig. 1 would apply? Yes. We don't recall seeing them in the literature, though. If this is deemed relevant, it is just a matter of changing `trans_reduced = TRUE` when we are simulating HESBCN models inside function `random_evam`.

You can of course construct the non-transitively reduced graphs "by hand" (creating the data frame with the appropriate structure) or, much simpler, using the Shiny web app.

7 H-ESBCN: details and examples of using `λs` and computing transition rate matrices and predicted genotype frequencies

Here I provide full details about how we interpret and use the results from the method described in Angaroni *et al.* (2021). I do this here because, in contrast to CBN or MHN, there is no existing previous code or examples that do this, and we found some potentially confusing issues. I have turned this into a specific section so as not to break the flow of the former sections.

7.1 Lambdas from the output: "Best Lambdas" and "lambdas_matrix"

The output returned by the H-ESBCN C code contains a "Best Lambdas" vector. The output returned by function `import.hesbcn` (that we have included in the code, in file `HESBCN__import.hesbcn.R`) has an object called "lambdas_matrix" where each of the lambdas for a gene is divided by the number of parents. This can be checked in any of the examples in the PMCE repository. Code that shows three examples, with XOR, OR, AND is available under "`inst/miscell/examples/HESBCN-lambdas-from-examples.R`".

It is the output from "Best lambdas" (i.e., the undivided lambdas) that are "[the] rates of the Poisson processes of the continuous-time HMM, associated with the vertices of the model, which allow one to estimate the expected waiting time of a node, given that its predecessor has occurred." (p. 756). (What is the division? An operation that modifies an internal data structure, and just a temporary operation, done merely for implementation purposes. In line 95 of the code —as of current version, in

<https://github.com/BIMIB-DISCo/PMCE/blob/main/Utilities/R/utils.R>— the divided lambdas are again summed, so the partition disappears: "`curr_in_lambda = sum(hesbcn$lambdas_matrix[,curr_node])`", and it is that value that is used in further downstream computations; email with the authors on 2021-07-09). The "Best lambdas" are returned by our modified `import.hesbcn` function.

7.2 Interpreting OR and XOR (and AND)

I find Figure 1C of Angaroni *et al.* (2021) possibly confusing. First, the non-confusing part: node "D" has a rate when exactly one of B XOR C has occurred, and node "G" some other rate when E or F or both E and F have occurred. (Note: the figure shows τ s, not λ s. The comments here refer to the λ s).

Now the (for me, at least) possibly confusing part: it seems that the node called "B xor C" is such that B and C have the same rates of dependencies on A; in other words, it would seem to imply that $\lambda_B = \lambda_C$. Similarly, the node called "E or F" seems to indicate that both E and F have the same rate, so $\lambda_E = \lambda_F$. But this need not be so. In fact, virtually all of the examples we have looked at, and the examples in their output, do not satisfy that the rates to the genes that are part of a XOR, OR, or AND relationship are the same. For instance, in the example above of Bladder Urothelial Carcinoma (see "inst/miscell/examples/HESBCN-lambdas-from-examples.R"), KMT2D depends on KMT2C and TP53, but the rate for KMT2C, $\lambda_{KMT2C} = 0.1991$ and that for TP53, $\lambda_{TP53} = 0.8062$.

Remember that the λ for a gene is the rate of the process until that mutation appears and is fixated, given all the dependencies of that gene are satisfied (which is, of course, the same interpretation as under CBN). Again: "[the] rates of the Poisson processes of the continuous-time HMM, associated with the vertices of the model, which allow one to estimate the expected waiting time of a node, given that its predecessor has occurred." (p. 756).

But the rate at which the parents are satisfied can differ (as it was the case for CBN). A difference with respect to CBN is that, with CBN, if a gene D depends on three genes A, B, C, regardless of the lambdas of each of A, B, C, D can only happen once all of A, B, C are present. With H-ESBCN and with OR and XOR relationships this is no longer the case: one can see D with only A, for example.

What if some genes depend with an AND, others with a XOR and others with a OR? Just apply the rules to each type of dependency: in the HESBCN model if a gene depends on a set of genes, it has the same type of dependency on all the genes of that set.

7.3 Predicted genotype frequencies

Once we have the transition rate matrix, obtaining the predicted genotype frequencies uses the same procedure as for CBN and MHN; see [section 3.1, "Predicted genotype frequencies for CBN, MCCBN, MHN, H-ESBCN"](#).

7.4 An example with OR and XOR

In this example:

- A, B, C depend on none.
- D depends, with an OR, on both A and B
- E depends, with an XOR, on B and C
- Transition rate matrix is shown below: rows are origin, column destination. λ s are those from "Best Lambdas".

(This example is also shown in [section 2.3.4, "Hidden Extended Suppes-Bayes Causal Networks \(H-ESBCN\)"](#)).

	WT	A	B	C	AB	AC	AD	BC	BD	BE	CE	ABC	ABD	ABE	ACD	ACE	BCD	BDE	ABCD	ABDE	ACDE		
WT		λ_A	λ_B	λ_C																			
A					λ_B	λ_C	λ_D																
B					λ_A			λ_C	λ_D	λ_E													
C						λ_A		λ_B															
AB								λ_C	λ_D	λ_E													
AC									λ_B				λ_C	λ_D	λ_E								
AD										λ_B				λ_D	λ_E								
BC										λ_A				λ_B									
BD											λ_A				λ_C	λ_D	λ_E						
BE											λ_A				λ_D								
CE												λ_A				λ_E							
ABC													λ_A										
ABD														λ_D									
ABE															λ_C								
ACD																λ_D							
ACE																	λ_B						
BCD																		λ_E					
BDE																		λ_A					
ABCD																			λ_A				
ABDE																				λ_A			
ACDE																					λ_A		

7.5 Three examples from actual analysis

- The code in inst/miscell/HESBCN-OR-XOR-AND-lambda-and-rates.R contains examples of how we use those lambdas (the `n`, number of steps, used is ridiculously small, and set to these tiny values just for the sake of speed).

1. OR

- Suppose output such as this (again, see file inst/miscell/HESBCN-OR-XOR-AND-lambda-and-rates.R for how to reproduce it).

```
$adjacency_matrix
  Root A B C D
Root    0 1 1 0 0
A        0 0 0 1 1
B        0 0 0 1 1
C        0 0 0 0 0
D        0 0 0 0 0

$lambdas_matrix
  Root      A      B      C      D
Root    0 8.083 2.585 0.000 0.0000
A        0 0.000 0.000 8.914 0.2062
B        0 0.000 0.000 8.914 0.2062
C        0 0.000 0.000 0.000 0.0000
D        0 0.000 0.000 0.000 0.0000

$parent_set
      A      B      C      D
"Single" "Single" "XOR" "OR"

$lambdas
[1] 8.0833 2.5854 17.8277 0.4124

$edges
  From To      Edge Lambdas Relation
1 Root  A Root -> A  8.0833  Single
2 Root  B Root -> B  2.5854  Single
3   A   C      A -> C 17.8277     XOR
4   B   C      B -> C 17.8277     XOR
5   A   D      A -> D  0.4124     OR
6   B   D      B -> D  0.4124     OR
```

- From the above output, these are the lambdas:
 $\lambda_A = 8.0833, \lambda_B = 2.5854, \lambda_C = 17.8277, \lambda_D = 0.4124$.
- Focusing only on A, B, D, to see gene D we can follow four paths.
 - The first two involve only two mutations:

- * $WT \rightarrow A \rightarrow AD$
- * $WT \rightarrow B \rightarrow BD$
- * The first is much faster, since the rate for the transition from WT to A is 8.1 compared to 2.6 of the transition B to D (from competing exponentials, the probabilities of moving to A and B are 0.76 and 0.24, respectively).
- In the other two paths D is the third gene to appear:
 - * $WT \rightarrow A \rightarrow AB \rightarrow ABD$
 - * $WT \rightarrow B \rightarrow AB \rightarrow ABD$
 - * These two paths take the same time, on average: both A and B need to appear (with rates given by λ_A, λ_B) and then we need D to appear (λ_D).
- Similarly, to get to genotype "A, B, D" we can follow these paths:
 - * $WT \rightarrow A \rightarrow AB \rightarrow ABD$
 - * $WT \rightarrow B \rightarrow AB \rightarrow ABD$
 - * $WT \rightarrow A \rightarrow AD \rightarrow ABD$
 - * $WT \rightarrow B \rightarrow BD \rightarrow ABD$
 - * All of them take the same expected time, as we need A, B, and D to happen, each governed by $\lambda_A, \lambda_B, \lambda_D$, respectively.
- In terms of fitness, if we used OncoSimulR (see additional document “Using OncoSimulR to get accessible genotypes and transition matrices”), we would write, for the fitness of AB: $(1 + \lambda_A)(1 + \lambda_B)$, for AD $(1 + \lambda_A)(1 + \lambda_D)$, and for ABD $(1 + \lambda_A)(1 + \lambda_B)(1 + \lambda_D)$.
 - Note, specifically, that genotypes *AD* and *BD* are not fitness equivalent, unless $\lambda_A = \lambda_B$.

2. XOR

- Using the above example, and focusing only on A, B, C, these are the only ways of seeing a C:
 - $WT \rightarrow A \rightarrow AC$
 - $WT \rightarrow B \rightarrow BC$
 - As we have a XOR, no routes can go through AB.
 - The first is much faster and common than the second ($\lambda_A = 8.1; \lambda_B = 2.6$).
 - Fitness (again, this is relevant if using, for example, OncoSimulR) of *AC* is $(1 + \lambda_A)(1 + \lambda_C)$ and of *BC* $(1 + \lambda_B)(1 + \lambda_C)$.

3. Both OR and XOR

- There is nothing new. As an example, gaining both C and D mutations.
 - $WT \rightarrow A \rightarrow AC \rightarrow ACD$
 - $WT \rightarrow B \rightarrow BC \rightarrow BCD$
 - $WT \rightarrow A \rightarrow AD \rightarrow ACD$
 - $WT \rightarrow B \rightarrow BD \rightarrow BCD$
 - There is no path going through *AB* since C has a XOR relationship on A and B.
 - In the first path we first need to wait for A to happen (rate λ_A) then C (λ_C) then D (λ_D).

- Same for the second, with B instead of A. The first path is much more common than the second.
- The third path transposes the order of occurrence of D and C, but takes the same average time as the third. Note that the fitness of the final genotype is the same through both routes, only the order of steps changes.
- The fourth path transposes the order of occurrence of D and C, but takes the same average time as the fourth. Note that the fitness of the final genotype is the same through both routes, only the order of steps changes.

7.6 Combining AND, OR, XOR?

Nothing changes. Use the rules for AND where there is an AND, XOR where there is a XOR, OR where there is an OR. Again, in the HESBCN model if a gene depends on a set of genes, it has the same type of dependency on all the genes of that set.

8 FAQ

8.1 In the figures, some times I get the error “Figure margins too large”

Solution: try to reduce the length of the gene names.

Longer explanation: It is impossible to accommodate, automatically, all possible use cases in terms of length of genotypes (e.g., you analyzed a data set with 10 genes, and some have names that are many characters long). We try to catch mistakes, but we might have missed some.

8.2 In the figures, some times genotype names are truncated

This problem is related to the previous one: with very large genotype or gene names, sometimes the only way to prevent the "Figure margins too large" error is to make figure margins smaller, which can result in truncation.

8.3 In the figures, some times the histograms are too tiny

Similar to previous problems: genotype or gene names are probably too large, so to accommodate them we need to make the rest of the plot smaller.

8.3.1 When data are saved, genes without mutations are excluded

When creating user data (for instance, when adding new genotypes), any gene that has no mutations is automatically excluded from the saved data, regardless of the setting for number of genes. This is a feature, not a bug. For example, suppose you set the number of genes to 3, but you only specify frequencies, or counts, for genotypes "A" and "A, B". The data set will only contain columns for genes A and B (since gene C has no mutations and it would be excluded during the analyses).

8.4 Why haven't you used method X?

We have included here what we believe are the current state-of-the-art methods that have existing public implementations that run in reasonable time. After searching the literature, we have included any method that could be deemed appropriate. We have, in fact, provided access to two very recent methods: H-ESBCN and OncoBN (and their github repos show we have contributed bug reports).

Among the remaining methods available, most of them do not seem to be developed nor used anymore. For some of these methods, their authors have developed newer methods that seem to have superseded the former methods. Some other methods have dependencies on external libraries that are not open source. And, of course, we cannot provide access to methods that have no software, or have software that will run only under proprietary systems. Some further comments are provided in S4_Text in Diaz-Uriarte and Vasallo (2019) (<https://doi.org/10.1371/journal.pcbi.1007246.s006>).

If you think we have overlooked a method that should be included, please let us know.

8.5 With OncoBN sometimes I obtain DAGs that are not transitively reduced

Yes, that can happen. See details here

<https://github.com/phillipnicol/OncoBN/issues/5>. There is an example of this in the additional examples.

8.6 In the DAG figures, why do nodes with two or more incoming edges have only a single annotated edge with a number?

Because the number, which is the λ (CBN, HESBCN) or θ (OncoBN) is the rate (CBN, HESBCN) or probability, conditional on the assumptions indicated by the DAG being satisfied. So the λ or θ are per node, not per edge. For instance, suppose gene C depends on both A and B (there is an AND); and you see a number of 0.7. That is the λ or θ for observing C mutated when both A and B are mutated.

And why then not annotate the nodes, instead of the edges? Because in our experience:

- Annotating nodes leads to more confusing figures.
- Annotating edges shows what transitions are likely/fast, an idea not conveyed by annotating nodes.

8.7 Do sampled genotype frequencies and counts contain observation noise? And predicted genotype frequencies?

For all models except OT, predicted genotype frequencies do not have observation noise added. The OT model itself estimates noise, and thus predicted frequencies obtained from models fitted to observed data incorporate observation noise. See “[CPMs: Error models](#)” ([section 2.3.6](#)).

When we obtain a finite sample from the predicted frequencies, you can decide to add observation noise with argument `obs_noise` to function `sample_CPMs`; what happens with OT depends on whether the predictions are from a simulated model or a model fit to observed data; see details in “[Error models and obtaining finite samples \(or sampled genotype counts\)](#)” ([section 5.2](#)).

8.8 I want to setup my own Shiny app with different default “Advanced options”

In file `EvAM-Tools/evamtools/inst/shiny-examples/evamtools/ui.R` search for “Advanced options” and modify the defaults to whatever you want.

8.9 How can I use the Shiny app in a local intranet with load balancing using multiple Docker instances

This is well beyond the scope of this document and there are many options available. One that can work (and this is more or less what we actually do) is the following:

- Start multiple Docker instances (say, 20) by changing the range of ports, for example, 3010 to 3030.
- Use HAProxy (<https://www.haproxy.org/>) so that you have a single entry point for all requests to the service that are then distributed, with load balancing, to the 20 instances. You will want to use “sticky connections” (see the HAProxy documentation).

As said above, this is just a sketch of the basic procedure. There are many other options.

8.10 If I use the Docker image for the package (`rdiaz02/evamrstudio`), can I run the Shiny app?

Yes, you can. Just start a browser as explained in the README (<https://github.com/rdiaz02/EvAM-Tools#how-to-run-the-r-package-from-the-docker-image>). Then, once in RStudio, in the R console type `runShiny()` and you will have the interactive Shiny app open. But even if you can do it, it is not clear why you'd want to do this: if you only want to run the Shiny app, the Docker image `rdiaz02/evamshiny` is lighter and the steps to launch it much faster.

8.11 Why aren't you using Shiny Server?

Because we did not see it as necessary or convenient. If you want to run Shiny interactively from an R session load `evamtools` and call function `runShiny`; no need for Shiny Server. If we want to run Shiny as a service, with Docker images it is rather straightforward to launch a bunch Docker instances and use HAProxy to access to them using load-balancing (see 8.9) or any other such similar solution.

Moreover, notice this in the Shiny Server documentation (<https://shiny.rstudio.com/articles/shiny-server.html>): “Shiny Server will host each app at its own web address and automatically start the app when a user visits the address. When the user leaves, Shiny Server will automatically stop the app.” That is not exactly what we want. We want the containers to be up and running, ready to answer requests as they come with minimal latency. Moreover, a single Shiny Server would have given access to a single instance of the app (so that if two or more users access the app, one of the users has to wait while R is busy executing what the other user is running); to give users access to multiple simultaneous instances we would have needed, for example, multiple Docker images each with its own Shiny Server.

However, we might be missing something; if you think Shiny Server would allow or ease some use cases, please let us know.

8.12 I want to build my own Docker images

If you want to modify the Docker images, modify the Dockerfiles: `Dockerfile-evam-rstudio` (for the RStudio Dockerfile that launches RStudio) or `Dockerfile-evam-shiny` (well, for the Dockerfile that creates the container to run shiny).

Then, from the ‘EvAM-Tools‘ directory run one or both of:

```
docker build -f Dockerfile-evam-shiny --tag somename .
docker build -f Dockerfile-evam-rstudio --tag somename .
```

You can now run these images, as explained in the README file..

Note: it is possible, and actually a better idea, to run docker without sudo; look at the Docker documentation: <https://docs.docker.com/engine/security/rootless/>).

8.12.1 What if creating the image fails because of no internet connection from the container

Creating the above image requires installing R packages and that might fail because the Docker container cannot connect with the internet. The following might help:

<https://superuser.com/a/1582710>, <https://superuser.com/a/1619378>. In many cases, doing `sudo systemctl restart docker` might be enough.

8.12.2 Cleaning the build cache and stale old images

Sometimes (e.g., if the base containers change or you want to remove build cache) you might want to issue

```
docker builder prune
```

or the much more drastic

```
docker system prune -a
```

Please, read the documentation for both.

8.12.3 Copying docker images from one machine to another

Yes, that can be done. See here, for example: <https://stackoverflow.com/a/23938978>

1 Introduction

Here we present examples, with both real and simulated data, that illustrate the use and utility of EvAM-Tools. We will start with the analysis of one cancer data set, trying to understand the

*Department of Biochemistry, Universidad Autónoma de Madrid, Instituto de Investigaciones Biomédicas “Alberto Sols” (UAM-CSIC), Madrid, Spain. Author for correspondence: r.diaz@uam.es

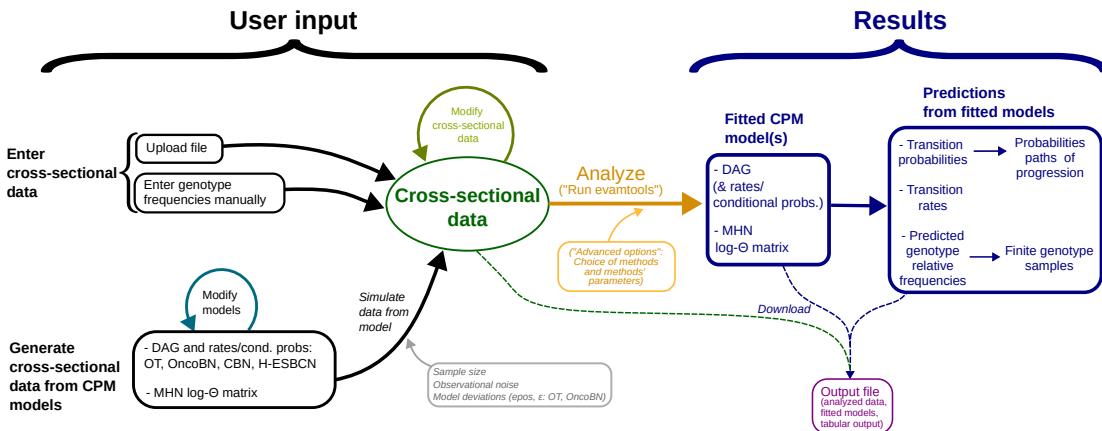

differences in the output of the different methods, and to do that we will also make use of flexibly modifying the genotype counts to run additional analyses. We will then show the analyses of a different cancer data set, which departs from the previous example in the patterns of differences and similarities between methods. Next, we use two short examples where we simulate data under a given model, and examine how different methods perform (whether or not they can recover the true signal). All the previous examples can be run in the web app, and that is what we use here. In the final section we discuss simulating random models, using the R package.

The objective of this document is not to provide complete analyses of any of the data sets, or address all of the questions mentioned above in full (that would require full papers). The objective is to illustrate the use of EvAM-Tools, especially its web app, and also to include some examples of output that, although not necessarily very common, are not unusual and can sometimes be surprising at first (e.g., the variability among fitted H-ESBCN models, in “*Is it just sample size?*”, section 2.2, or output with DAGs that are not transitively reduced in “*A model with AND*”, section 4.3).

1.1 Web app: overview of workflow and use cases, and relationship to these examples

On the web app landing page, under “About EvAM-tools” (<https://www.iib.uam.es/evamtools/#overview>) we provide an overview of the workflow and use cases. For completeness we repeat that material here, indicating, in bold, how the examples in this document relate to the major functionalities and workflows discussed there.

The figure below provides an overview of the workflow with the web app:

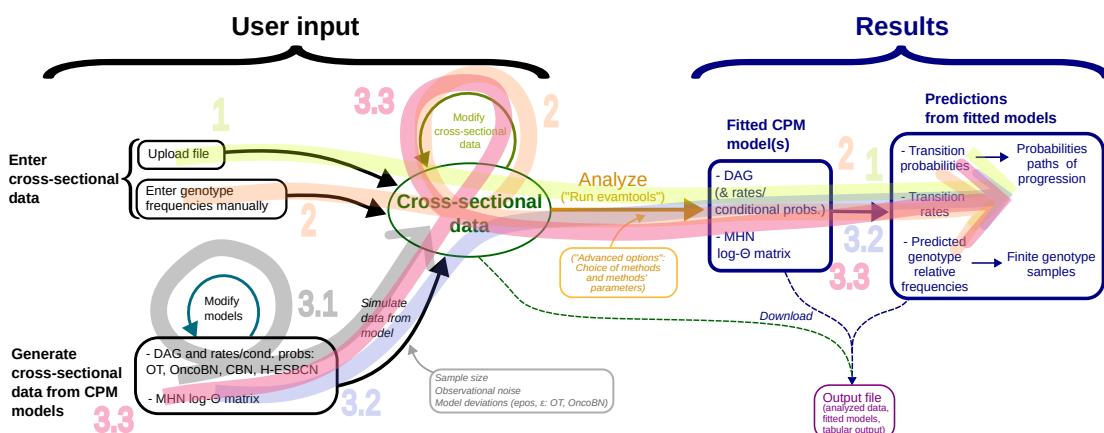

The web app encompasses, thus, different major functionalities and use cases, mainly:

1. Inference of CPMs from user data uploaded from a file. Examples “*Analyzing the BRCA data set*” (section 2.1) and “*Analyzing the ovarian CGH data*” (section 2.3).
2. Exploration of the inferences that different CPM methods yield from manually constructed synthetic data. Example “*Is it just sample size?*” (section 2.2) uses a modification of uploaded data to explore changes in sample size; example “*Analyzing manually constructed synthetic data*” (section 3) constructs synthetic data to examine the effect of aliasing of events.
3. Construction of CPM models (DAGs with their rates/probabilities and MHN models) and simulation of synthetic data from them.

- 3.1. Examination of the consequences of different CPM models and their parameters on the simulated data. Examples “*What happens if we increase ϵ for OncoBN?*” (section 4.1.1), “*A simple exploration of MHN*” (section 4.1.2).
- 3.2. Analysis of the data simulated under one model with methods that have different models (e.g., data simulated from CBN analyzed with OT and OncoBN). Examples “*A model with AND, XOR, OR*” (section 4.2) and “*A model with AND*” (section 4.3).
- 3.3. Analysis of the data simulated under one model after manual modification of specific genotype frequencies (e.g., data simulated under CBN but where, prior to analysis, we remove all observations with the WT genotype and the genotype with all loci mutated). Example “*Modifying data generated from a CPM model before analysis*” (section 4.4).

The figure below highlights the different major functionalities and use cases, as numbered above, over-imposed on the previous figure:

Furthermore, note that in all cases, when data are analyzed, in addition to returning the fitted models, the web app also returns the analysis of the CPMs in terms of their predictions such as predicted genotype frequencies and transition probabilities between genotypes. Most of the examples below illustrate this, showing, for example, the predicted genotype frequencies and transition probabilities.

2 Analysis of cross-sectional data

We will analyze two cancer data sets, the ovarian cancer CGH data included in the Oncotree package (Szabo and Pappas, 2013), and the BRCA data set for basal-like subtypes (from Cerami *et al.*, 2012; Gao *et al.*, 2013, originally from Cancer Genome Atlas Research Network, 2012; see Supplementary File S5_Text, <https://doi.org/10.1371/journal.pcbi.1007246.s007> of Diaz-Uriarte and Vasallo, 2019 for full details about data origins and preprocessing).

So that you can use these data sets directly, we provide them in the repository (https://github.com/rdiaz02/EvAM-Tools/tree/main/examples_for_upload). The direct links are:

- BRCA_ba_s.csv: https://raw.githubusercontent.com/rdiaz02/EvAM-Tools/main/examples_for_upload/BRCA_ba_s.csv
- ov2.csv: https://raw.githubusercontent.com/rdiaz02/EvAM-Tools/main/examples_for_upload/ov2.csv

In section “[Appendix: getting the BRCA and Ov data sets from the R console](#)” (section 6) we show how to obtain the data from the R console.

2.1 Analyzing the BRCA data set

We now import the BRCA csv data set, BRCA_ba_s.csv, into the web app, <https://iib.uam.es/evamtools>. We go to the “User input” tab, and click, on the left, on “Upload file”; we set the “Name for data” as “BRCA_ba”):

The screenshot shows the 'User input' tab of the EvAM-tools web application. On the left, there's a sidebar with options like 'Cross-sectional data.', 'Upload, create, generate, modify.', and 'Enter cross-sectional data:' with two radio button options: 'Upload file' (selected) and 'Enter genotype frequencies manually'. The main area has a title 'Upload data (CSV format)' with a 'Help' button. It includes a text input for 'Name for data' containing 'BRCA_ba', a 'Load Data' button with a 'Browse...' sub-button, and a message 'No file selected'. Below this is another section titled 'Change genotype's counts' with a 'Help' button, featuring a search bar and tabs for 'Index', 'Genotype', and 'Counts'.

On “Load Data” we click on “Browse” and select the file from our file system; the data is uploaded, and the genotypes’ frequencies are shown in the histogram on the right and the table at the bottom (where, if we wanted, we could modify the genotype counts):

Cross-sectional data.

Upload, create, generate, modify:

Enter cross-sectional data:

Upload file
 Enter genotype frequencies manually

Generate cross-sectional data from CPM models:

DAG and rates/cond. probs.
 MHN log- Θ matrix

Examples and user's data:

BRCA_ba

evamtools R package version: 2.1.12

Upload data (CSV format)

[Help](#)

If you want to give your data a specific name, set it in the box below before uploading the data. File names should start with a letter, and can contain only letters, numbers, hyphen, and underscore, but no other characters (no periods, spaces, etc.).

Name for data

Load Data No file selected

Change genotype's counts

[Help](#)

Search:

Index	Genotype	Counts
1	WT	9
2	PNPLA3	1
3	TP53	57
4	TRIM6	1
5	ATP2B2, TP53	1
6	PIK3CA, TP53	6
7	RB1, TP53	2
8	TP53, TRIM6	3
9	PNPLA3, RB1, TP53	1

To delete (or reset) all genotype data upload a new (or the same) data file.

Rename the data

Give the (modified) data a different name that will also be used to save the CPM output. Names should start with a letter, and can contain only letters, numbers, hyphen, and underscore, but no other characters (no periods, spaces, etc.)

Give your data a name

Run evamtools

Advanced options and CPMs to use

Genotype	Counts
WT	9
PNPLA3	1
TP53	57
TRIM6	1
ATP2B2, TP53	1
PIK3CA, TP53	6
RB1, TP53	2
TP53, TRIM6	3
PNPLA3, RB1, TP53	1

Before running the analysis, we select the unselected H-ESBCN as one of the methods to run (under “Advanced options and CPMs to use”). We also set the number of MCMC iterations to 500000, instead of 200000, for increased stability of results; this increase in iterations will of course result in longer running times.

We click “Run evamtools” and the output is shown in about 30 to 50 seconds¹. For easier display of the figures in this document, we select first three of the methods to show, by clicking, on the left menu, under “Customize the visualization”:

¹In this example, changing the setting for the number of MCMC iterations of H-ESBCN from 100000 to 500000 is responsible for increasing the total time from about 30 to about 50 seconds.

Data name

Customize the visualization

- CPMs to show CBN
 OT
 OncoBN
 MHN
 H-ESBCN

This is the output from the first three methods (CBN, OT, OncoBN):

And this from the next two methods (MHN, H-ESBCN):

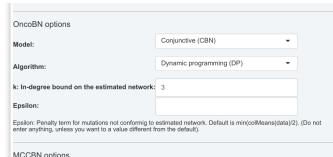

(The above screen-captures only show the DAGs/MHN matrix; we are not showing the figures of the predictions of the fitted models, such as transition probabilities or predicted genotype relative frequencies).

EvAM-Tools makes it immediate to see that:

- The output from OncoBn and OT is essentially identical.
- CBN and H-ESBCN give very different DAGs.
- OT and OncoBN differ from both CBN and H-ESBCN.

That OT and OncoBN give identical results is not surprising since OncoBN has not found any disjunctive pattern and OncoBN is using the disjunctive (OR relationships) model. We can run OncoBN using the conjunctive model. Go back to “User input” and click on “Advanced options and CPMs to run” and set, for “OncoBN options”, the “Model” to “Conjunctive”:

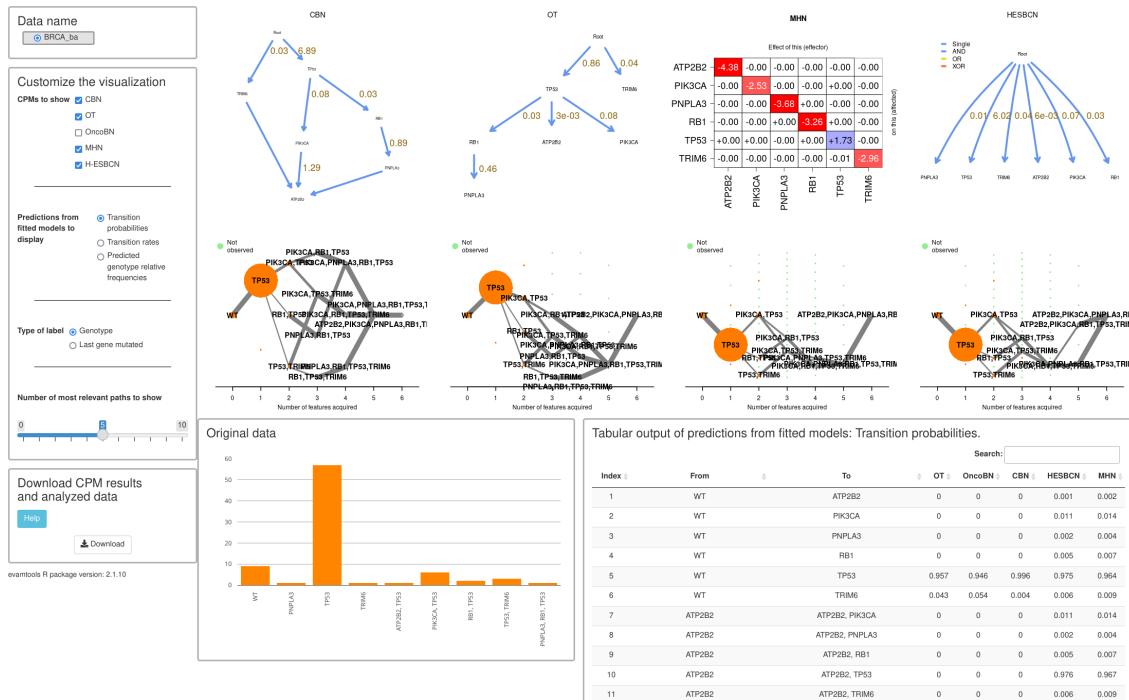

Click on “Run evamtools” to obtain the new fit (since we are only interested in rerunning OncoBN, we might want to unclick the other methods, so as to make the run as fast as possible). Interestingly, if we run OncoBN with conjunctive pattern, it does not show any conjunctions either (the result is the same as shown above):

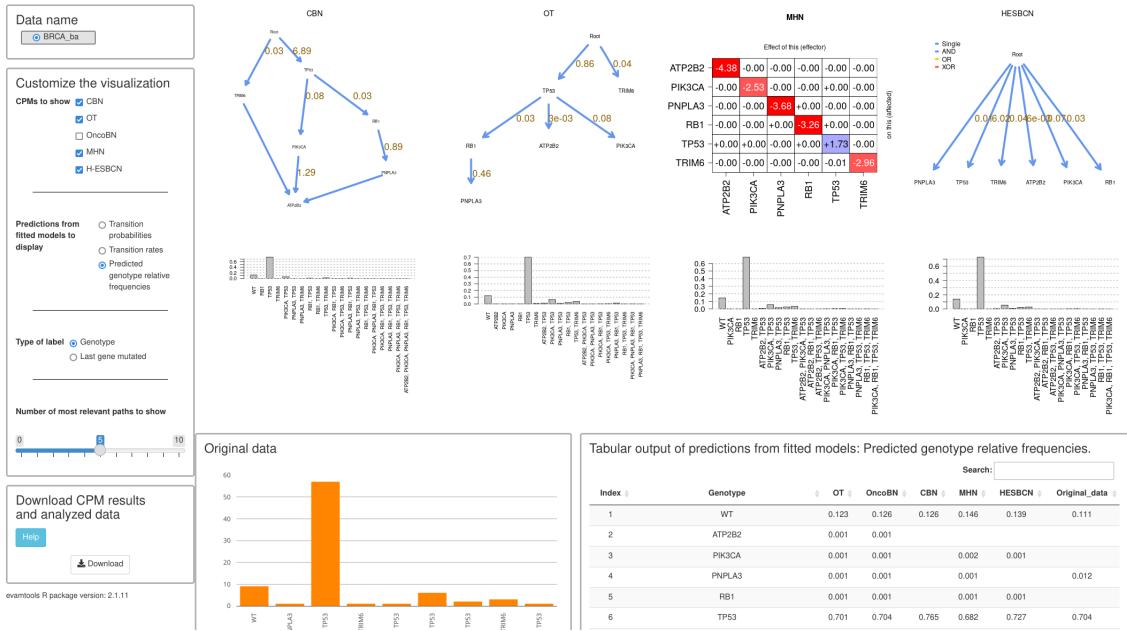

Thus, CBN seems to find support in the data for conjunctive dependencies that neither OncoBN (run using the “Conjunctive” model) nor H-ESBCN find.

EvAM-Tools’s output also displays, in the Results tab, the original data as well as transition probabilities, transition rates, and predicted genotype relative frequencies. We show the three differing DAGs, MHN’s output, and the data, when we select “Transition probabilities” (tabular output truncated in the screen capture):

and when we select “Predicted genotype relative frequencies”:

(This, incidentally, shows that we probably would have wanted to use shorter genes names as the histogram labels are too long).

From the above display we can conclude:

- The data contain very few cases where there are joint occurrences of two or more genes: most joint occurrences appear only once.
- The conditional probabilities from OncoBN (or OT) indicate that the really likely event is gaining TP53; the conditional probability of the remaining ones is very small.
- CBN leads to the same conclusion: the only large λ is that for TP53.
- MHN’s output points in the same direction: except for TP53, the diagonal entries of the matrix are all negative and large in absolute value, and the off-diagonal entries are all essentially 0. Thus MHN’s model is saying that we can fit the data reasonably well without modeling inhibiting or facilitating relations between genes.

Therefore, we can conclude that the apparently different results are caused by differences in the weighting of evidence: H-ESBCN, given the very small frequencies of most genotypes with more than one mutation, is choosing not to take those as evidence of dependencies, and is instead returning a simpler model.

2.2 Is it just sample size?

We can examine more carefully the conjecture above: would H-ESBCN return a different DAG if sample size were much larger but relative proportions were the same? We can do that easily with EvAM-Tools. We simply go to the “User input” tab and multiply the genotype counts, for example by 10 (which is trivially done by clicking on each cell and adding a 0).

We rename the data first, and then increase the sample size. This is what it looks like:

About EvAM-tools User input Results

Cross-sectional data.

Upload data (CSV format)

[Help](#)

If you want to give your data a specific name, set it in the box below before uploading the data. File names should start with a letter, and can contain only letters, numbers, hyphen, and underscore, but no other characters (no periods, spaces, etc.).

Name for data:

Load Data:

Change genotype's counts [Help](#)

Search:

Index	Genotype	Counts
1	WT	90
2	PNPLA3	10
3	TP53	570
4	TRIM6	10
5	ATP2B2, TP53	10
6	PIK3CA, TP53	60
7	RB1, TP53	20
8	TP53, TRIM6	30
9	PNPLA3, RB1, TP53	10

To delete (or reset) all genotype data upload a new (or the same) data file.

Rename the data

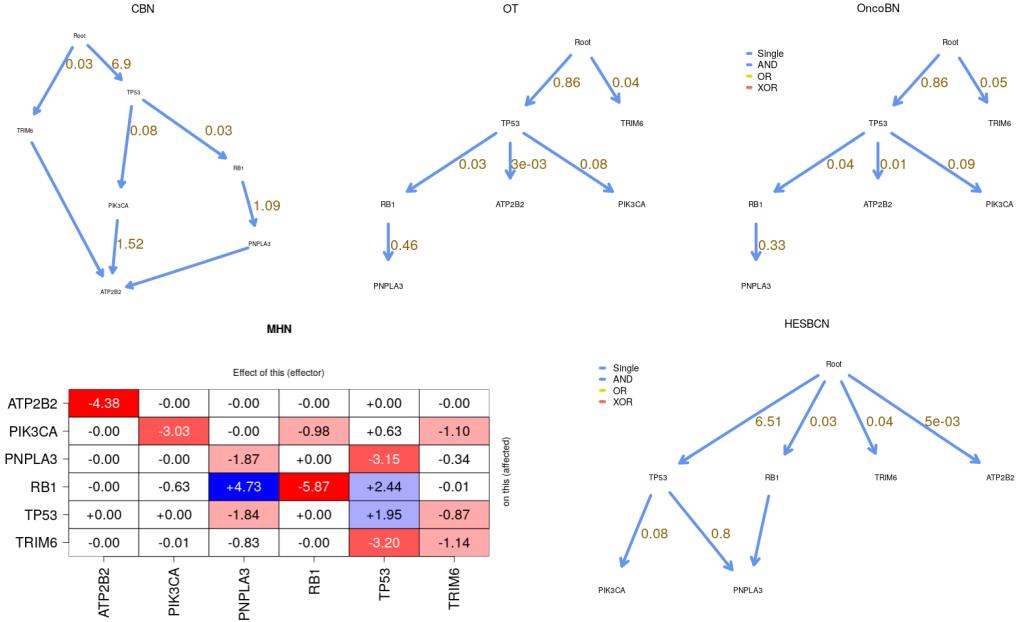

Give the (modified) data a different name that will also be used to save the CPM output. Names should start with a letter, and can contain only letters, numbers, hyphen, and underscore, but no other characters (no periods, spaces, etc.)

Give your data a name:

Run evamtools

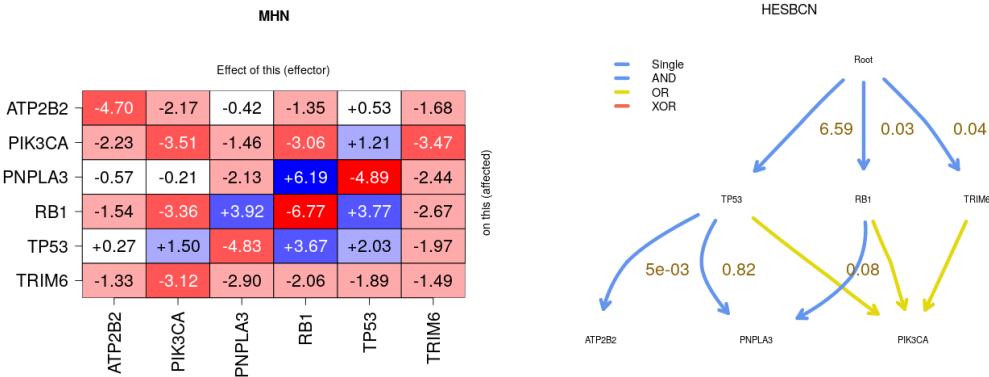

Advanced options and CPMs to use

Now, we rerun the analyses:

The DAGs and weights (lambdas, probabilities) are the same for OT, OncoBN and CBN. But the models inferred by MHN and H-ESBCN have both changed, and the second now includes dependencies between some of the genes. Some of these dependencies are similar to the ones in the CBN output (PNPLA3 depends on RB1 and TP53; PIK3CA depends on TP53).

Interestingly, increasing the sample size another 10 times results in additional changes in the MHN and H-ESBCN models (OT, OncoBN, and CBN only show minor changes, not shown below):

Note that in some runs, the output returned by H-ESBCN is different from the one above; with H-ESBCN different runs can sometimes lead to different results. You can fix the random number seed in “Advanced options” to prevent this, though this is probably not advisable, since fixing the seed would precisely prevent us from seeing the instability of the fitted models. For example, if you set the number of MCMC iterations (under “Advanced options”) to 100000 and the seed to 19, you will obtain a model with an XOR². In the web app we use, by default, 200000 MCMC iterations,

²Note, though, that the output with the XOR also contains an edge with an extreme weight, which makes this model suspect; more detailed exploration would use a range of seeds, and possibly change also the number of MCMC iterations to run

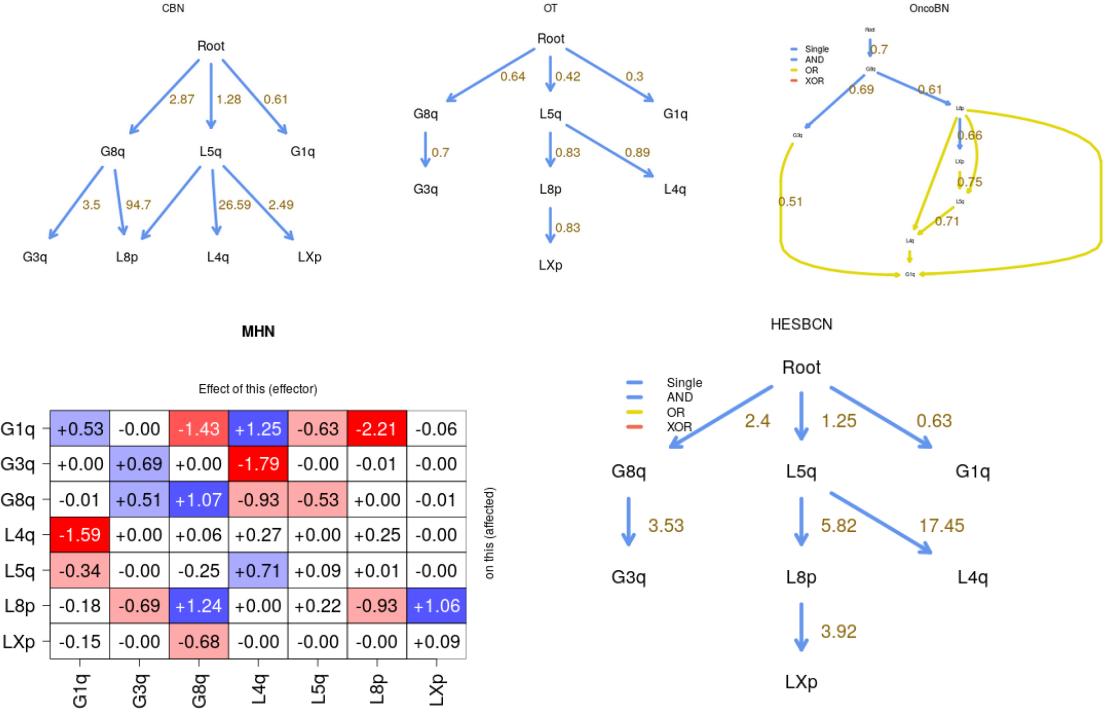

a number larger than the default in <https://github.com/danro9685/HESBCN>, precisely to minimize this instability). In the examples in this document we use an even larger number of 500000 MCMC iterations to obtain more robust results and because none of the examples shown take longer than about 1 minute to run. Variability of results from different runs can also be observed with CBN sometimes (though, in our experience, it is less common than with H-ESBCN with default parameters).

These results lead us to conclude tentatively that, compared to OT, CBN, and OncoBN, the penalties used in H-ESBCN and MHN seem to have a larger effect on models fitted to modest sample sizes.

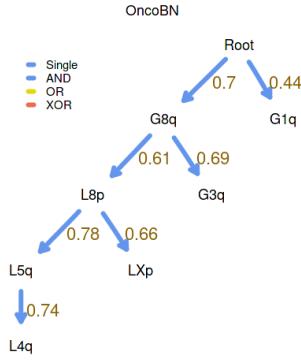

2.3 Analyzing the ovarian CGH data

Lest readers think that the above (coincidence between OT and OncoBN, and H-ESBCN returning star models with moderate sample sizes) are general patterns, we now show, for a different example, the analyses of the ovarian CGH data. We upload the data `ov2.csv` and, as before, include H-ESBCN in the methods and set the number of MCMC iterations of H-ESBCN to 500000.

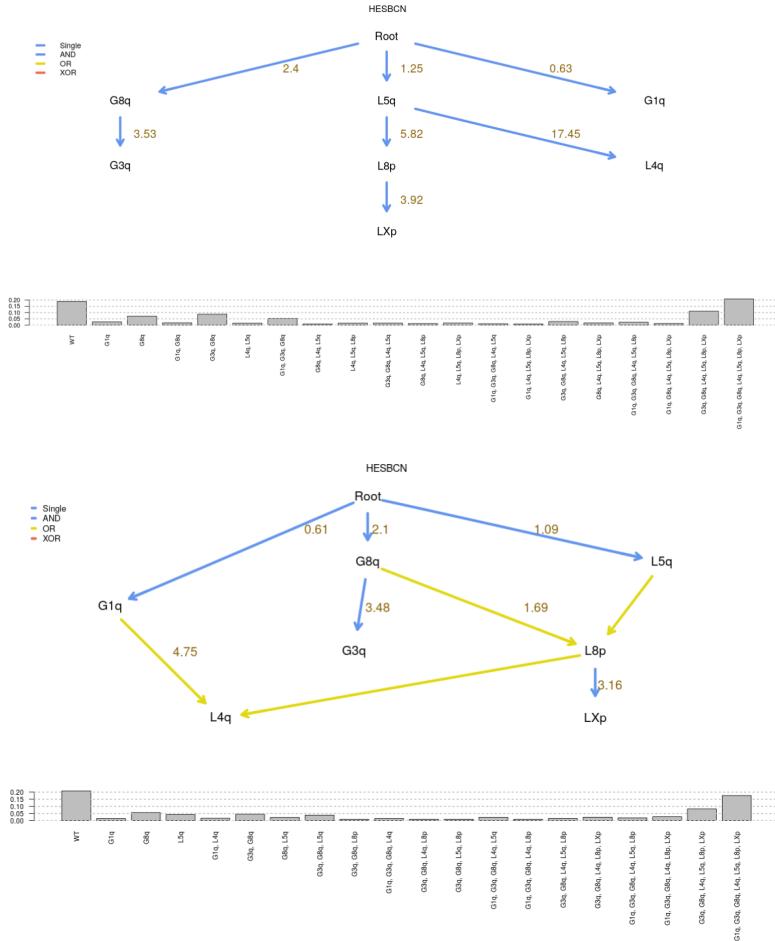

This is the output from the web app (run takes a little bit over one minute):

And we re-run the OncoBN model using the “Conjunctive” options (instead of the default disjunctive —we did this before in section “[Analyzing the BRCA data set](#)”, section 2.1, and it involves going back to “User input”, clicking on “Advanced options and CPMs to run” and setting, for “OncoBN options”, the “Model” to “Conjunctive”). This is the output:

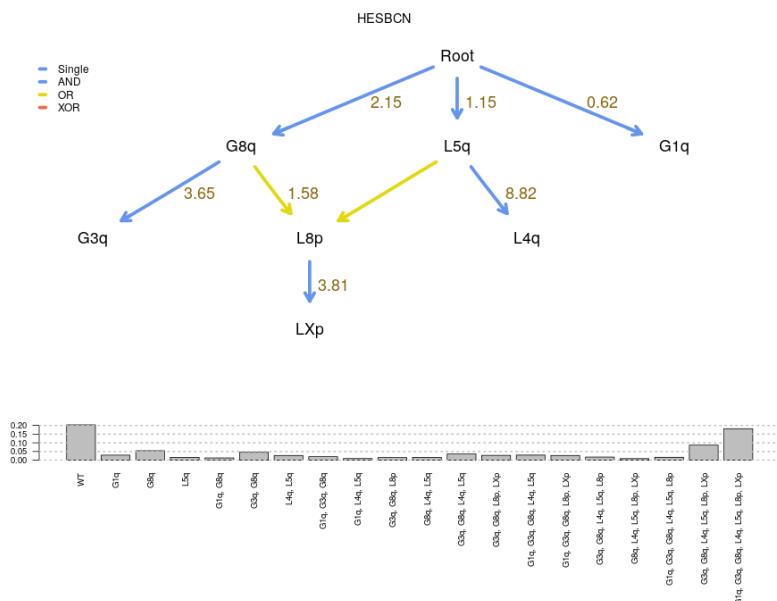

Interestingly, in the above run, H-ESBCN gives an identical structure to that of OT (parameters are, of course, different: OT’s weights are conditional probabilities and H-ESBCN λ s are rates). Different runs of H-ESBCN can give different results, such as the following ones, where we also ask the web app to display the predicted genotype frequencies:

We can increase the number of MCMC iterations. When using 1000000 most runs tend to give

this model:

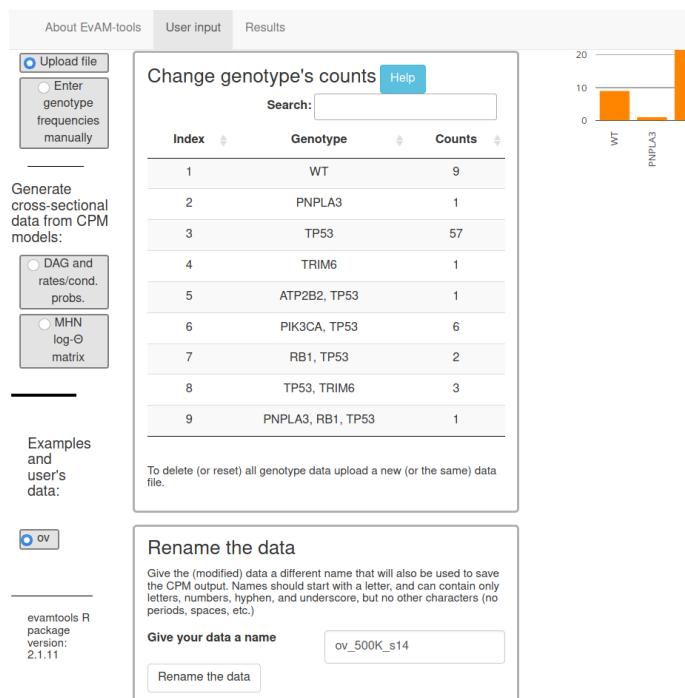

The variability between fitted H-ESBCN models might deserve a more careful exploration and, in “for real” analyses, additional runs with 1000000 iterations or even more.

Now there are large similarities between OT and CBN (though, of course, there can be no conjunctions in OT). H-ESBCN finds identical restrictions for G3q (3q+) and G8q (8q+) as OT and CBN; it also finds similar patterns to OT for L5q and LXp; note that CBN shows $L5q \rightarrow L8p$ and $L5q \rightarrow LXp$ and that H-ESBCN shows an OR for the dependency of L8p on G8q and L5q, whereas CBN, which can only model ANDs, places an AND. OncoBN using the default disjunctive relationship (OR, but not XOR) seems to suggest quite a different model (note that H-ESBCN can also fit OR relationships). Interestingly, the conjunctive model for OncoBN is similar, but not identical, to the ones from OT and CBN.

2.4 Using the web app for small computational experiments

We have shown the output of repeated runs of H-ESBCN, changing the number of MCMC iterations and possibly setting different random number seeds. GUIs and web apps are not the most appropriate tools for a systematic exploration; instead, properly documented code as an R script would be the preferred procedure. For small experiments, however, the web app is fine. A simple way to keep track of what is done is as follows:

1. Upload the data, giving it a meaningful name (under “Name for data”); for example, ov.
2. Go to the “Rename the data” box, and add the settings you will use to the name of the data; for example, for 500000 MCMC iterations with seed 14 for H-ESBCN enter ov_500K_s14 in “Give your data a name”, and **click on “Rename the data”**.

3. Under “Advanced options and CPMs to use” set the seed to 14 and the number of MCMC iterations to 500000, possible also setting H-ESBCN as the only method to run.
4. Click on “Run evamtools”.
5. Repeat steps 2 to 4 as needed.

The “Results” tab will contain the output of the different runs, properly labeled so we can examine, at will, outputs from runs with different settings.

3 Analyzing manually constructed synthetic data

We will create some synthetic data to show the consequences of analyzing data where two events are indistinguishable, because they are completely aliased, i.e., indistinguishable, because they have identical patterns —identical columns in the data matrix—. Of course, manually constructed synthetic data can be used to explore or examine many other patterns, unrelated to aliased events.

From the “User input” tab we select the “Enter genotype frequencies manually”:

About EvAM-tools

Cross-sectional data. Upload, create, generate, modify:

Enter cross-sectional data:

Upload file
 Enter genotype frequencies manually

Now, we enter some WT, for example, 20 WT observations. We select no mutations, and type a “20” in “Counts”:

Add genotypes

WT is added by not clicking on any mutations.

Any gene without mutations is excluded from the data, regardless of the setting for number of genes.

For the CPM analysis, if any gene is always observed mutated (i.e., has a constant value of 1 for all observations), one observation with no genes mutated is added to the sample before the analysis.

For the CPM analysis, genes that have identical patterns (i.e., that lead to identical columns in the data matrix), are fused into a single gene.

Mutations A B C D

Counts

Add genotype

And when we click on “Add genotype” we see the histogram with 20 WT and the genotype table with the 20 WT:

We now add 15 observations with only A mutated (i.e., 15 individuals of genotype A), and 12 with both B and C (i.e., 12 individuals with genotype “B, C”); we first click on “A” on “Mutations” putting a 15 in “Counts”

Add genotypes

WT is added by not clicking on any mutations.

Any gene without mutations is excluded from the data, regardless of the setting for number of genes.

For the CPM analysis, if any gene is always observed mutated (i.e., has a constant value of 1 for all observations), one observation with no genes mutated is added to the sample before the analysis.

For the CPM analysis, genes that have identical patterns (i.e., that lead to identical columns in the data matrix), are fused into a single gene.

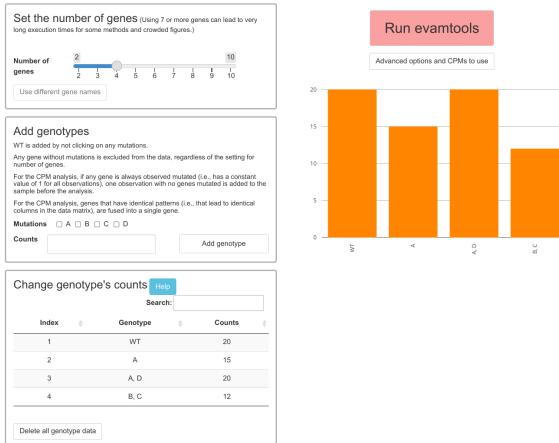

Mutations A B C D

Counts

Add genotype

and then on “Add genotype”. We next click on B and C in “Mutations” putting a 12 in Counts. We finally add 20 individuals with the “A, D” genotype (steps as before: click on A and D for mutations, and put a 20 in counts). After these steps, we can see the genotype composition as both

a histogram and table:

So that it is easier to go back to these data, we give this data set a name, for example “Aliased_1” under “Rename the data”.

The 'Rename the data' section has the following fields:

- Give your data a name: Aliased_1
- Renaming button: Rename the data

Click the “Rename the data” button, so the name is used and you will see it listed on the left, under “Examples and user’s data:”

The 'Examples and user's data:' section lists:

- 1
- 2
- 3
- 4

Below this are several radio buttons for selection:

- Empty
- Linear
- AND
- OR
- XOR
- Aliased_1

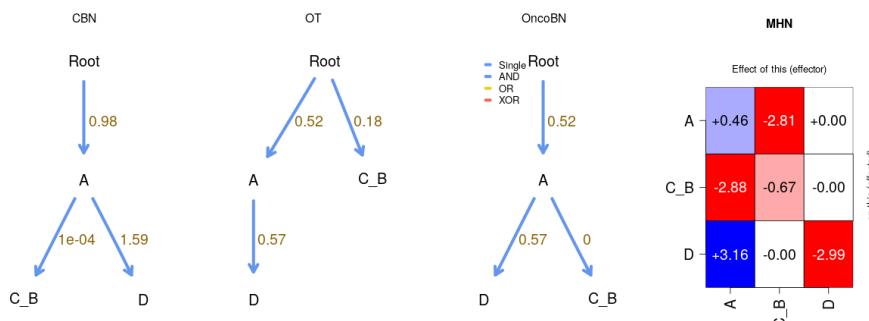

There is also a 'Delete all genotype data' button.

Below this is the 'Rename the data' section:

- Give your data a name: Aliased_1
- Renaming button: Rename the data

At the bottom, it says: evamtools R package version: 2.1.12

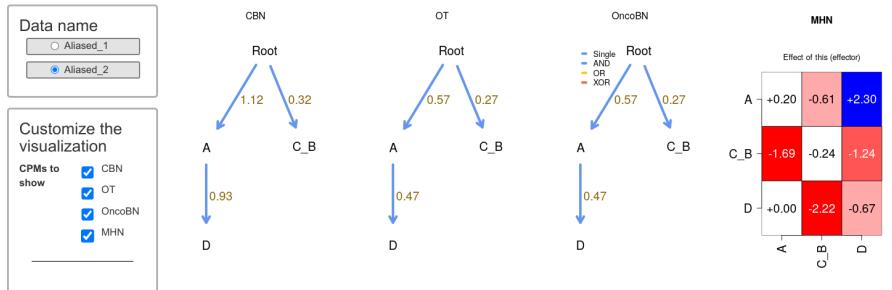

Now we click on “Run evamtools”. These are the fitted models (we did not use H-ESBCN here):

In the DAGs and the MHN log Θ matrix, as well as the transition probabilities, an event

labelled “C_B”. “C_B” is the name of the event created automatically by EvAM-Tools by fusing the “C” and “B” events that are not distinguishable.

Note also that the models fitted by the DAGs, for example OncoBN or CBN, do not seem right when we look at the parameters of the “C_B” event. That is because there are no “A, B, C” events, and we would expect to see some if A on the one hand, and B and C on the other, are occurring independently. We will add some observations (eight, for example) with all of A, B, C. We go back to the “User input” tab, we “Rename the data” to “Aliased_2” (so that the new modifications we are about to make do not affect “Aliased_1”), and we add genotype “A, B, C” with a count of 8. And we click on “Run evamtools”. This is the output

which is more sensible. Notice, however, that we still have “C_B” as an event because, in fact, they remain completely aliased, indistinguishable. This aliasing would be broken by adding just a single “C” or a single “B”, or a single “A, C”, or “A, B”, or “B, D” or “D, C” or any “A, B, D” or “A, C, D”.

4 Generating data from known models

The discussion in sections “*Analyzing the BRCA data set*” (section 2.1) and “*Analyzing the ovarian CGH data*” (section 2.3) has used CPMs on two cancer data sets for which the truth is unknown. To understand the differences between models, and the performance characteristics of different methods, we can simulate data under a known model and examine if the true pattern can be recovered. This is very easy to do with EvAM-Tools and addresses two commonly asked questions:

- Can we recover the true structure?
- How do different methods perform when data has been generated under the assumptions of another method?

This is what we will do below in examples “*A model with AND, XOR, OR*” (section 4.2) and “*A model with AND*” (section 4.3). But EvAM-Tools is also useful to understand what different models imply in terms of the data we would observe, even without considering what each method would fit to a given observed data set; this is what we show in “*CPM models: what type of data they imply?*” (section 4.1).

4.1 CPM models: what type of data they imply?

4.1.1 What happens if we increase ϵ for OncoBN?

We go to “User input” and, by default, the option “DAG and rates/cond. probs” is selected under “Generate cross-sectional data from CPM models”. We can leave the default DAG in the selected

“DAG_Fork_4”. In “Type of model” under “Define DAG” we click on “OncoBN”:

Define a Directed Acyclic Graph (DAG) and generate data from it. [Help](#)

1. Define DAG

Type of model

Model: OT OncoBN CBN/H-ESBCN

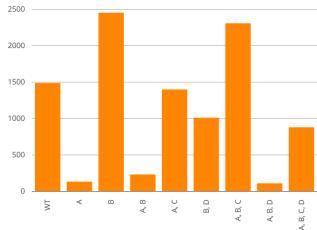

and you can see that the last column of the DAG table is now called “theta”:

DAG table

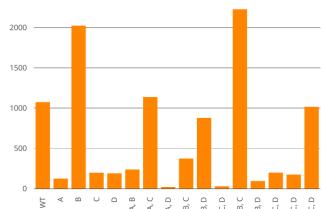

Remember to hit Ctrl-Enter when you are done editing the DAG table for changes to take effect.

From	To	Relation	theta
Root	A	Single	0.5
Root	B	Single	0.7
A	C	Single	0.9
B	D	Single	0.3

Now, click on “Generate data from DAG”; to make patterns easier to observe, set the “Number of genotypes to sample” to a large number, such as 10000. If we look at the histogram we will see something similar to this one:

In particular, notice how the following genotypes are not observed: “A,D”, “B, C”, “B, C, D”, “A, C, D”, as they are not possible if the restrictions are completely respected. Now, increase “epos, ϵ ” to, say, 0.15, and click again on “Generate data from DAG”; now we will observe at least a few cases of all or most of the above four genotypes, as the predicted genotypes now incorporate deviations from the model.

We could continue increasing the value of ϵ ; this will result in increasing frequencies of the above four genotypes, and a decrease in WT. Very large increases in ϵ will lead to a blurring of the signature of this DAG.

A more advanced exploration of the role of deviations from the model in OT and OncoBN compared to the role of observational noise would alter “epos, ϵ ” with and without simultaneously changing the value of “Observational noise”.

4.1.2 A simple exploration of MHN

To try to gain a quick intuitive understanding of the multiplicative hazards model of MHN we go to “User input” and then click on “MHN log- Θ matrix”

Generate cross-sectional data from CPM models:

DAG and rates/cond. probs.

MHN log- Θ matrix

To start with a simple, yet not completely trivial, model, we set the number of genes to three:

Set the number of genes (Using 7 or more genes can lead to very long execution times for some methods and crowded figures.)

Number of genes

Use different gene names

Now, we click on “Generate data from MHN model”:

Define MHN's log-Theta matrix (log- Θ) and generate data from it. [Help](#)

1. Define MHN's θ s
Entries are lower case thetas, θ s, range $\pm \infty$
Remember to hit Ctrl-Enter when you are done editing the matrix for changes to take effect.

A	B	C
0	0	0
0	0	0
0	0	0

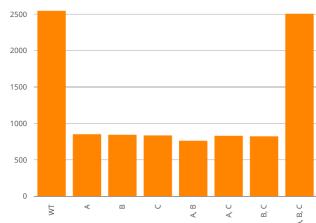

2. Generate data from the MHN model

Number of genotypes to sample

Observational noise (genotyping error)

[Generate data from MHN model](#) [Reset log- \$\Theta\$ matrix and delete genotype data](#)

In this model, there are not multiplicative effects between genes. This is what we obtain (again, it might help to increase the Number of genotypes to sample to 10000 to decrease the role of random sampling noise and focus on the predicted genotype frequencies):

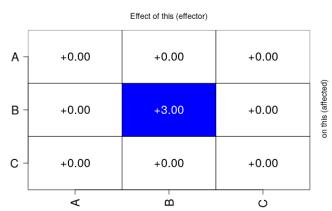

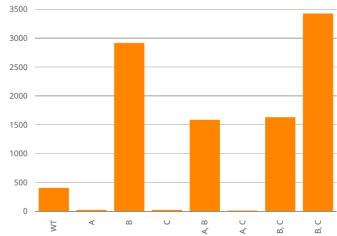

Effect of this (effector)

		on this (effector)		
		A	B	C
		A	B	C
A	+0.00	+0.00	+0.00	
B	+0.00	+0.00	+0.00	
C	+0.00	+0.00	+0.00	

Let us now increase the baseline hazard of event B. For example, set $\log-\Theta_{2,2} = 3$. (Modify the

entry, and click on Ctrl-Enter). The figure changes dramatically and all genotypes that have “B” have increased their frequency:

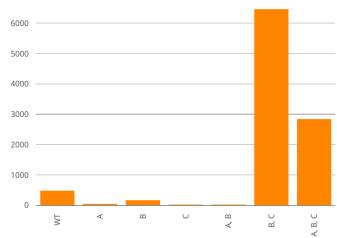

Let us now create a very large promoting effect of B on C; for that, we enter, for example, a 4 on the matrix entry (3, 2): $\log\Theta_{3,2} = 4$:

Notice how genotype B is more common than either A or C, but now whenever there is B it frequently in combination with C (very larger frequencies of genotypes B,C and A,B,C).

But what if B also has an inhibiting effect on A? Set $\log\Theta_{1,2} = -2$:

Effect of this (effector)		
		on this (selected)
		-
A	+0.00	-1.00
B	+0.00	+3.00
C	+0.00	+4.00

Notice how the frequency of genotype A,B,C has gone down (and also, though it is harder to appreciate, that of A,B).

4.2 A model with AND, XOR, OR

Here, we will simulate data under a model that includes both AND, OR, and XOR relationships (e.g., H-ESBCN). EvAM-Tools, in its web app, already includes such a model for five genes:

User input

Define a Directed Acyclic Graph (DAG) and generate data from it. [Help](#)

1. Define DAG

Type of model
Model: OT OncoBN CBN/H-ESBCN

New Edge
From (parent node) Root A B C D E
To (child node) A B C D E

[Add edge](#) [Remove edge](#)

If you want to decrease the number of genes first remove edges and nodes from the DAG and only then modify 'Set the number of genes'. (We cannot know which edges/nodes you want to remove).

If you want to increase the number of genes use 'Set the number of genes' to increase the available gene labels, and then increase the number of nodes in the DAG.

DAG table
Remember to hit Ctrl-Enter when you are done editing the DAG table for changes to take effect.

From	To	Relation	Lambdas
Root	A	Single	0.7
Root	B	Single	0.8
A	C	AND	0.9
B	C	AND	0.9
A	D	OR	0.4
B	D	OR	0.4
A	E	XOR	0.5
B	E	XOR	0.5

evamtools R package version: 2.1.11

2. Generate data from the DAG model

epos, ϵ

For OT (epos) and OncoBN (ϵ) only: probability that children nodes not allowed by the model (the DAG) occur. Accepted values: [0, 1]. This setting affects predicted probabilities.

Number of genotypes to sample

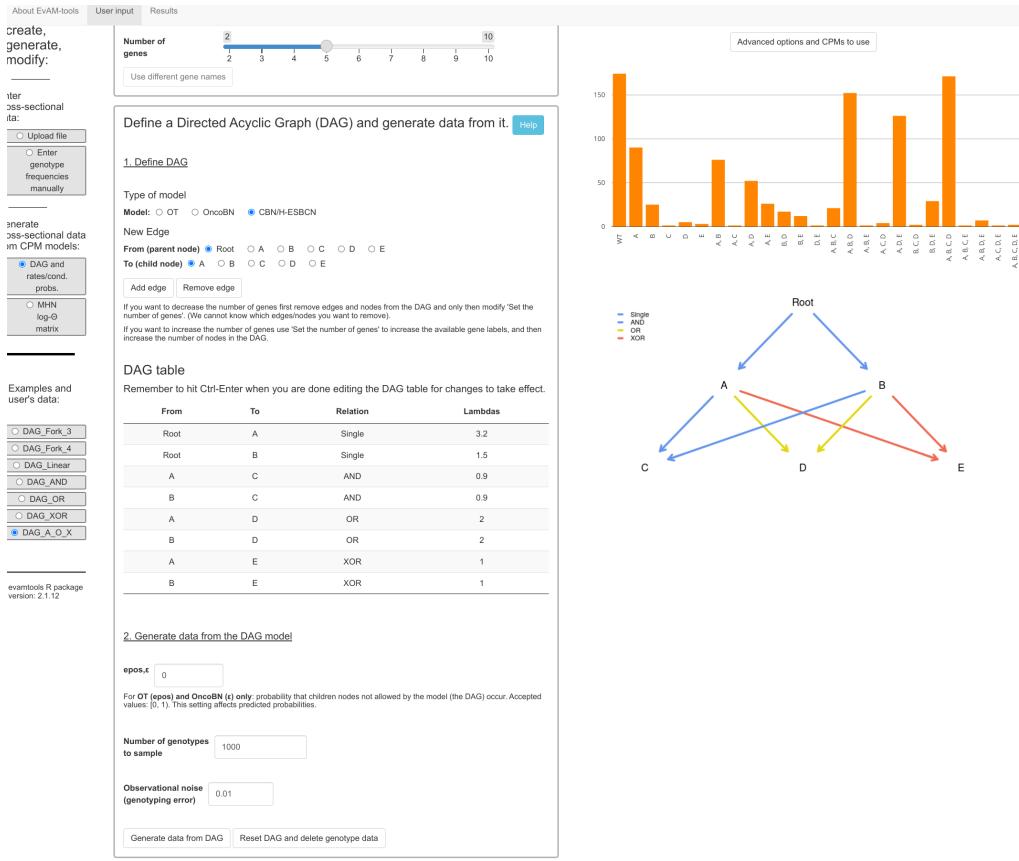

Observational noise (genotyping error)

[Generate data from DAG](#) [Reset DAG and delete genotype data](#)

Legend:
— Single
— AND
— XOR

If we want, we can change values (rates, relationships, noise, etc). We will change the rates of A, B, D, and E, setting them to 3.2, 1.5, 2, and 1, respectively; we set the number of genotypes to sample to 1000 and we will add 1% of Observation noise (i.e., we will type 0.01 in the “Observational noise (genotyping error)” box). Then, we click on “Generate data from DAG”,

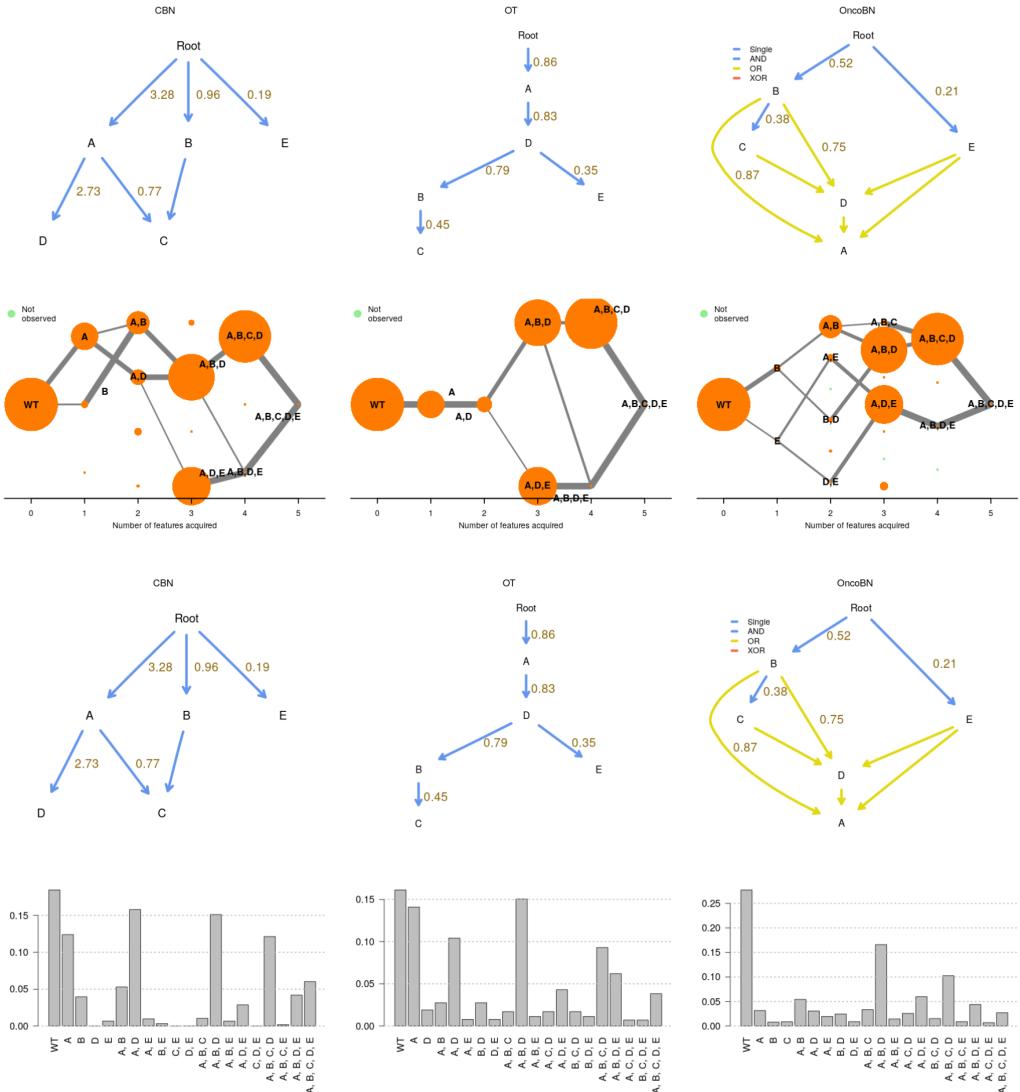

and obtain data simulated under that model:

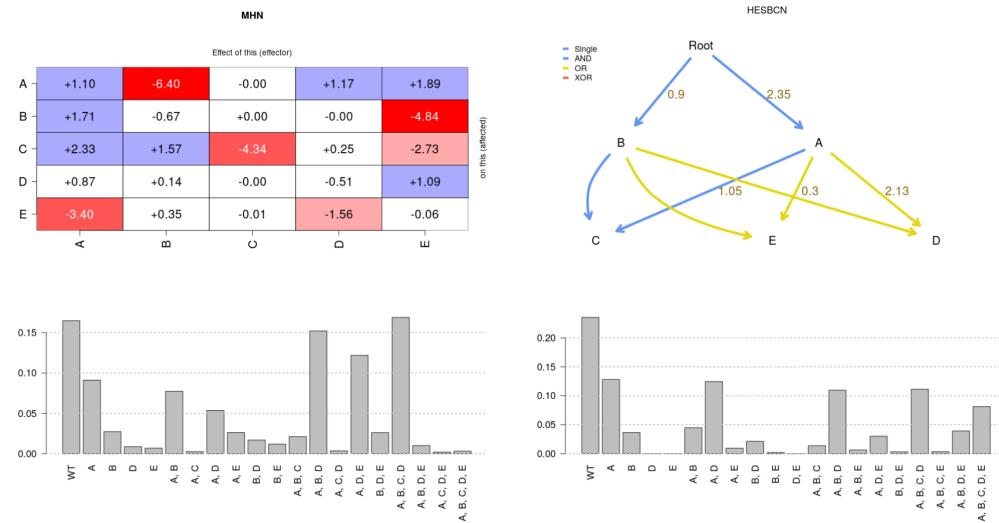

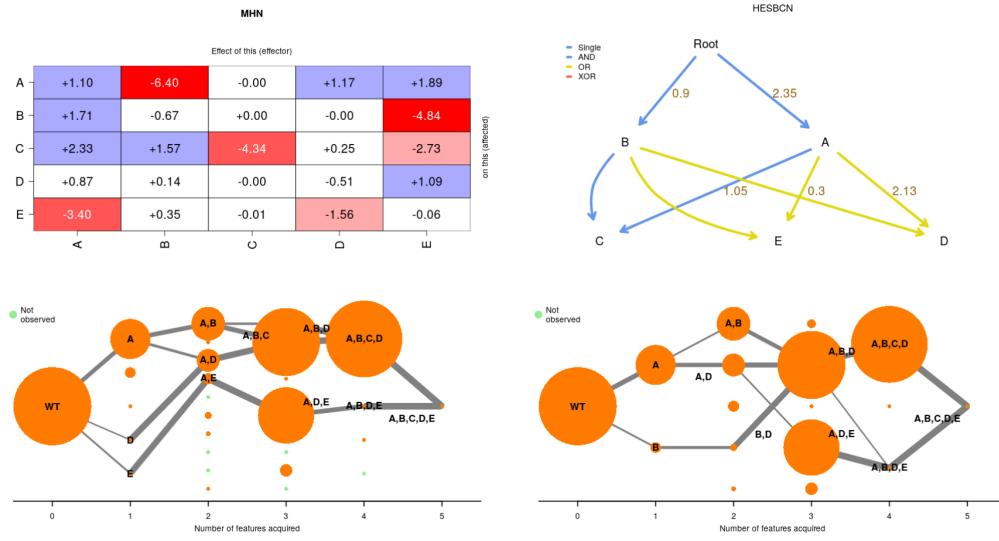

(Of course, the actual simulated data you are likely to obtain will vary differ from this one).

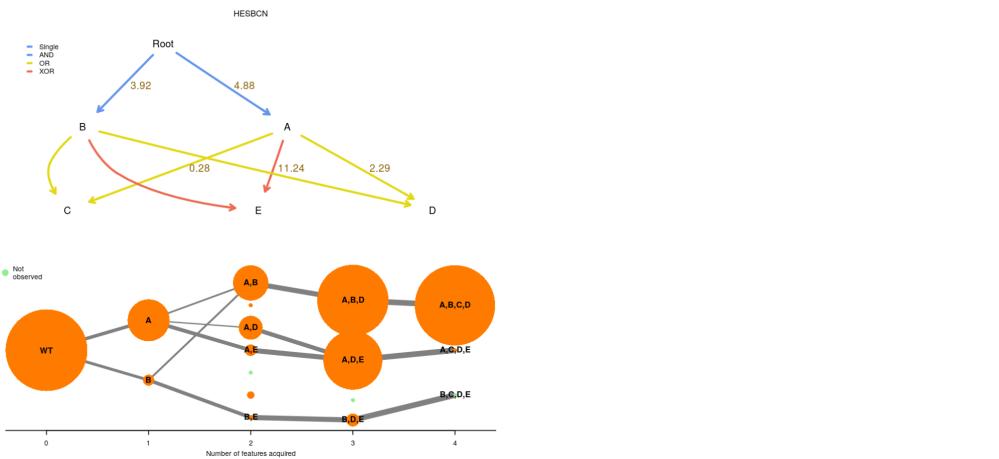

Now, we click “Run evamtools”, after adding H-ESBCN to the set of methods and setting its number of MCMC iterations to 500000 (again, this is done under “Advanced options and CPMs to use”). After about 30 seconds we obtain the output. In the plots below, and as we did before, we split it into three and two methods so it is easier to see. We show the models with two of the predictions: transition probabilities and predicted genotype relative frequencies (these predictions are also shown in the table, which we do not show below).

Note that the histograms of predicted genotype frequencies display, at most, the 20 most frequent genotypes (because of reasons of limited plotting space); all predicted genotypes are shown in the table.

And, as has been the case before, repeated runs of H-ESBCN can lead to different results, for example:

None of OT, CBN, or OncoBN can capture XOR relationships. But in this case, H-ESBCN incorrectly infers an XOR for D (it is really an OR) and an OR for C (it is really an AND).

We could increase the sample size by 10 by just setting “Number of genotypes to sample” to 10000 or add different levels of noise, etc.

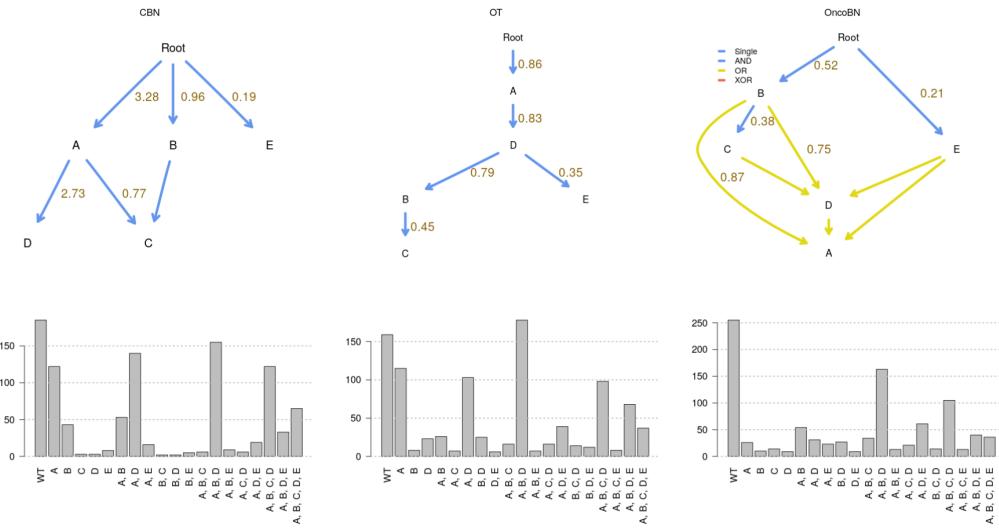

We could also ask to get, as return, not only the predicted genotype relative frequencies, but sampled genotype counts with, possibly, some noise added. Even without noise added, the relative frequencies of the sampled genotype counts would differ from the predicted genotype relative frequencies just because of sampling noise. We can do that by going back to the “User input” tab, clicking on “Advanced options and CPMs to use” and setting “Sample genotypes” to TRUE and selecting the number of samples, which here we set equal to the sample size of original data set (i.e., 1000); we also set the observation noise to 0.01.

The screenshot shows the 'Run evamtools' interface. At the top, there's a note about the number of genes (using 7 or more genes can lead to very long execution times for some methods). Below it, a slider for 'Number of genes' ranges from 2 to 10, with 10 selected. A link 'Use different gene names...' is present. A red button 'Run evamtools' is at the top right. Below the slider, a section titled 'Define a Directed Acyclic Graph (DAG) and generate data from it.' has a sub-section '1. Define DAG'. It includes a 'Type of model' dropdown with 'Model: OT' selected, and checkboxes for 'CBN', 'OncobN', 'MHN', and 'H-ESBCN', with 'CBN' checked. A note says 'CBN is the fastest method to use. H-ESBCN often takes much longer than the remaining methods (unless MHN). For 7 or more genes, CBN can be much slower than OT, OncobN, or MHN (e.g., data analysis in < 1 second by those three methods can take 47 seconds CBN)'. Below this, there's a note about removing edges and nodes from the DAG. A 'DAG table' section follows, with a note to hit Ctrl+Enter after editing. The table shows a single row: Root → Tc, Relation: Single, Level: 0.0. A note says 'Remember to hit Ctrl+Enter when you are done editing the DAG table for changes to take effect.' At the bottom, 'Advanced options and CPMs to use' is expanded, showing 'CPMs to use: CBN, OncobN, MHN, H-ESBCN' and 'Return paths to maximum: FALSE'. A note says '(Paths to the maximum and their probabilities. These are not part of the tabular or graphical output (because of their many edges). Return paths to maximum are included in the tabular output for convenience)'.

We hit on “Run evamtools” and, as before, we get the output but we now have one extra possible “Predictions from fitted models to display”:

And this is the output for three of the models; notice the added variability (i.e., how the relative heights and even the actual genotypes present are not the same as in the predicted genotype counts):

Of course, you can switch from displaying “Sampled genotype counts” to displaying “Predicted genotype counts” just by clicking on the button on the left.

4.3 A model with AND

Let us use now a model with AND; we use the preselected “DAG_AND”, with 1000 observations and a 5% (0.05) genotyping error. Remember to click on “Generate data from DAG” after changing the noise level:

```

Legend:
— Single
— AND
— OR
— XOR

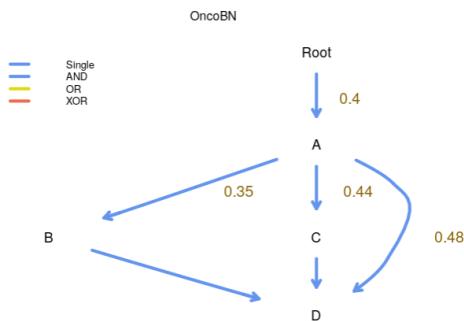

These are the fitted models:

H-ESBCN incorrectly infers the AND as an OR. CBN correctly infers the underlying model and provides estimates of the parameters that are very close to the true ones. OT and OncoBN cannot infer the correct true dependencies: OT because it cannot fit DAGs, but only trees (i.e., each node has only one parent) and OncoBN because it was run in disjunctive mode (OR relationships). We can run OncoBN using the conjunctive model; we have done this before (sections “[Analyzing the BRCA data set](#)”, section 2.1 and “[Analyzing the ovarian CGH data](#)”, section 2.3) and it involves going to “Advanced options and CPMs to run” and setting, for “OncoBN options”, the “Model” to “Conjunctive”:

This is the output we get:

This correctly identifies the joint dependency of D on both B and C, but there is also an edge between A and D that we would never observe with CBN (as CBN always returns the transitively reduced DAGs); this is a technical issue beyond the scope of this document, but one that we have

discussed in the OncoBN repo³.

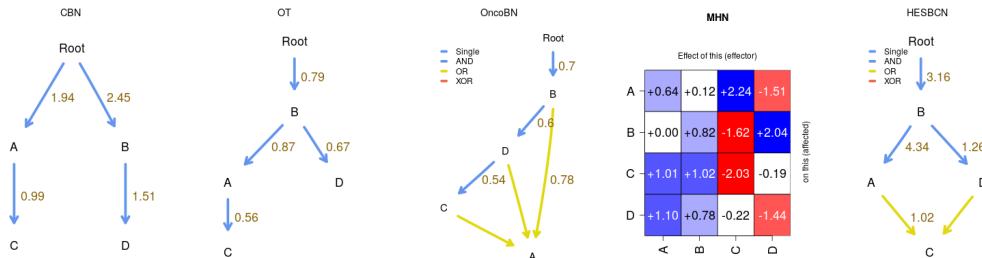

For H-ESBCN the returned model also includes an edge, the one between A and B, that is not necessary: since B depends on C and C depends on A, having B depend with an AND on both A and C is not needed (i.e., the transitive reduction of that DAG would remove the edge from A \rightarrow B). Note also that removing the A \rightarrow B arrow does not affect the relationships with D. Of course, for the relationships between C, B, and D we should not return the transitive reduction (as that would break the OR of D on either C or B). Thus, a model without the $A \rightarrow B$ would generate the exact same predictions as the model returned by H-ESBCN. (Why does this happen with H-ESBCN? It is a consequence of the heuristic search over DAG structures, which can occasionally return these topologies).

4.4 Modifying data generated from a CPM model before analysis

What if the data came from a given model but some additional process had altered the genotype data? For example, suppose data really came from a CBN model, but the frequency of WT genotypes is too small because the data have been filtered to contain only genotypes with at least one driver mutation, or the data contain some contaminated samples that would never had become tumors and have an excess of WT. We can explore this by generating data from a CPM model and, then, modifying the genotype composition, as we did in section “*Is it just sample size?*” (section 2.2) when we modified uploaded data.

As an example, go to “User input”, “DAG and rates/cond. probs”, and use the default selected “DAG_Fork_4”. Change lambdas to 2, 2.5, 1, 1.5, for A, B, C, D, respectively. Add 1% of observational noise. And set the “Number of genotypes to sample” to 5000, to ensure small sample sizes are not the culprit of different inferences. Click on “Generate data from DAG” and, for simplicity, then analyze the data with OT, OncoBN, CBN, MHN, and H-ESBCN.

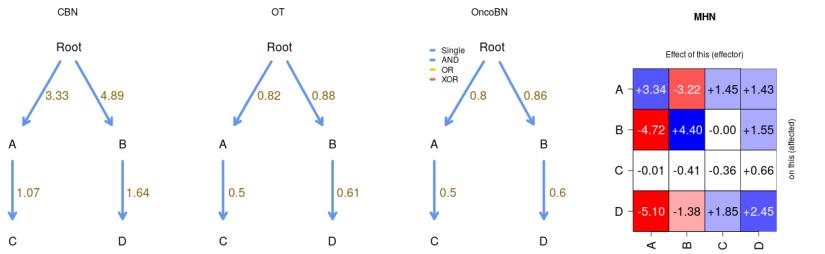

This is the output:

CBN correctly infers the DAG and the estimates of the λ s are close to the true ones. The other methods are not able to infer this model correctly.

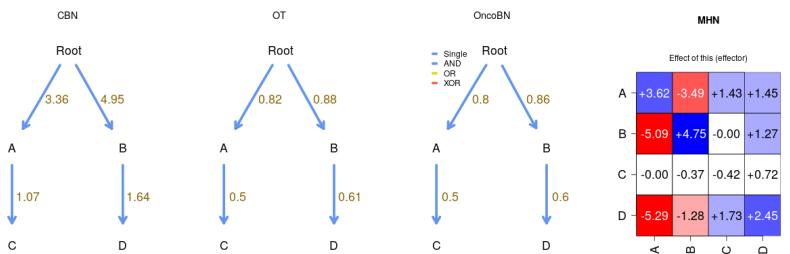

Now, go back to the “User input”. Before modifying the data, and to keep a copy of the originally generated one, on the “Rename data” type a name (e.g., “data_original”) and click on “Rename data”. Now, enter a new name in “Rename data”, for example “data_few_wt”, click on “Rename data”, and modify the WT frequency; I change it from its original value of 912 to 9. And then, analyze the data clicking on “Run evamtools”. This is the output:

³<https://github.com/phillipnico1/OncoBN/issues/5>

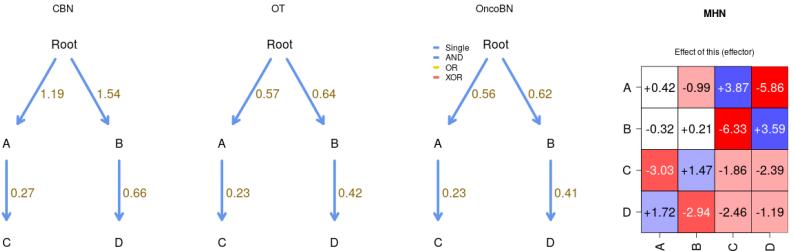

OT and OncoBN get the structure right, and for CBN the main consequence is altering the rates of A and B, increasing them (which is what we would expect). MHN also has increased estimates of $\log-\Theta_{A,A}$ and $\log-\Theta_{B,B}$ when we reduced the frequency of WT.

What if we removed the WT completely? We go back (and, if it is not the selected one, click, on the left, under “Examples and user’s data”, on “data_original”), and set WT to 0 (possibly after creating a new data set, “data_no_wt”) and analyze them:

The effect is minor, which is not surprising, since the large cut in WT had been going from 912 to 9.

We could, instead, eliminate all the observations with the four mutations (e.g., maybe they are too lethal to ever be observed?). We go to “User input”, select, on the left, “data_original”, rename it (“no_all_mut”), and set to 0 the A,B,C,D genotype.

The DAG structures for CBN, OT, OncoBN are preserved, but now H-ESBCN has modeled an XOR; the XOR models is not actually present, but unless there are XOR or similar phenomena, models with AND and OR cannot model the absence of A,B,C,D, given the relatively high frequencies of the rest of the genotypes (the CBN model, for example, has decreased the estimates of all the λ s).

We could also, as mentioned at the beginning of this section, increase the number of WTs. Etc, etc. We will not pursue this any further here. The key message from this section is that EvAM-Tools makes it very simple to examine targeted, specific, deviations in genotype composition from the genotype composition generated by a CPM model.

5 Simulating random CPMs/evams

If we were interested in systematically examining the performance of the different methods under different models, simulating random CPM (or evam) models is crucial. This type of work (generating and analyzing large numbers of simulations) is not suited for a web app, but it can be easily done with the R package. The key function here is `random_evam`.

```
## Load the package
library(evamtools)
## For reproducibility
set.seed(3)
he_r1 <- random_evam(ngenes = 5, model = "HESBCN")
he_r1$HESBCN_model

##   From To      edge    Lambda Relation
## 1 Root A Root -> A 0.6656892 Single
## 2 Root B Root -> B 1.1189358 Single
## 3 A   C       A -> C 1.8736265 Single
## 4 A   D       A -> D 2.0159447 XOR
## 5 A   E       A -> E 1.6987091 Single
## 6 B   D       B -> D 2.0159447 XOR

## Now, simulate a data set of size 200 from that model
## with 5% genotyping error

he_s1 <- sample_evam(he_r1, N = 200, obs_noise = 0.05)

## Analyze this data with all the methods except MCCBN (for speed)

he_s1_anal <- evam(he_s1$HESBCN_sampled_genotype_counts_as_data,
                     methods = c("CBN", "OT", "OncoBN",
                                "HESBCN", "MHN"))

## Show the fitted DAGs
he_s1_anal[grep1("_model", names(he_s1_anal))]

## $OT_model

## E  1.31 -0.44  2.19 -0.32 -2.13

```

This is just one example; serious simulation studies would examine exhaustively a range of scenarios. And we could, of course, compare other output, such as the predicted genotype frequencies, or the probabilities of paths to the maximum (use argument `paths_max = TRUE` when calling `evam`), etc. But this should be enough to show you how EvAM-Tools can be used to systematically compare the performance of different methods in different scenarios.

6 Appendix: getting the BRCA and Ov data sets from the R console

Here we show how to obtain, from the R console, the two data sets used in section “[Analysis of cross-sectional data](#)” ([section 2](#)). We simply export those data in a CSV format that can be uploaded to the web app.

```
## Load the package to access the BRCA data
library(evamtools)
data(every_which_way_data)

## You can check the names here, which are the same
## as in Suppl File S5 Text of Diaz-Uriarte & Vasallo, 2019
## names(every_which_way_data)

write.csv(every_which_way_data[["BRCA_ba_s"]],
          file = "BRCA_ba_s.csv", row.names = FALSE,
          quote = FALSE)

## Now export the ovarian cancer CGH data
library(Oncotree)

## Loading required package: boot

data(ov.cgh)

## Rename column names: they start with a number and
## finish on a "+" (gain) or "-" (loss), so automatically
## reading these column names removes the +/- and adds an
## "X" as the first character. Let us have columns start
## with L or G for loss/gain.

new_cn <- stringi::stri_sub(colnames(ov.cgh), 1L, 2L)
new_cn <- paste(ifelse(grep1("+", colnames(ov.cgh), fixed = TRUE),
                      "G", "L"), new_cn, sep = "")
ov2 <- ov.cgh
colnames(ov2) <- new_cn
write.csv(ov2,
          file = "ov2.csv", row.names = FALSE, quote = FALSE)
```

Package ‘evamtools’

September 26, 2022

Type Package

Title Tools for evolutionary accumulation models or event accumulation models (evam), for now mainly cancer progression models

Version 2.1.13

Date 2022-09-26

Author Ramon Diaz-Uriarte [aut, cre]
Pablo Herrera-Nieto [aut]
Daniele Ramazzotti [ctb],
Rudolf Schill [ctb]

Maintainer Ramon Diaz-Uriarte <r.diaz@uam.es>

Description Wrappers to run cancer progression models (CPMs) on cross-sectional data, including Conjunctive Bayesian Networks (CBN ---and their MC-CBN version---), Oncogenetic trees (OT), Mutual Hazard Networks (MHN), Hidden Extended Suppes-Bayes Causal Networks (H-ESBCNs ---PMCE---), and Disjunctive Bayesian Networks (DBN, from the OncoBN package). Tools to represent, graphically, the fitted models (DAGs of restrictions or matrix of hazards, as appropriate), the transition matrices and transition rate matrices (where appropriate) between genotypes and to show frequencies of genotypes sampled from the fitted models. Functions to sample from the fitted models or from random models to facilitate comparing different methods. An interactive Shiny web app allows users to easily visualize the effects of changes in genotype composition and to interactively modify and create datasets from models defined from scratch.

evam	<i>Runs the CPMs (or evams)</i>
------	---------------------------------

Description

Executes all CPMS given a cross sectional data set.

Usage

```
evam(x,
      methods = c("CBN", "OT", "HESBCN", "MHN", "OncoBN", "MCCBN"),
      max_cols = 15,
      cores = detectCores(),
      paths_max = FALSE,
      mhn_opts = list(lambda = 1/nrow(x),
                      omp_threads = ifelse(cores > 1, 1, detectCores())),
      ot_opts = list(with_errors_dist_ot = TRUE),
      cbn_opts = list(
        omp_threads = 1,
        init_poset = "OT"
      ),
      hesbcn_opts = list(
        MCMC_iter = 100000,
        seed = NULL,
        reg = c("bic", "aic", "loglik"),
        silent = TRUE
      ),
      oncobn_opts = list(
        model = "DBN",
        algorithm = "DP",
        k = 3,
        epsilon = min(colMeans(x)/2),
        silent = TRUE
      ),
      mccbn_opts = list(
        model = "OT-CBN",
        tmp_dir = NULL,
```

```

    addname = NULL,
    silent = TRUE,
    L = 100,

    adaptive = TRUE,
    thrds = 1L,
    verbose = FALSE,
    seed = NULL)
)

```

Arguments

x	cross sectional data
methods	Methods to use. A vector with one or more of the following strings, “OT”, “OncoBN”, “CBN”, “MCCBN”, “MHN”, “HESBCN”.
max_cols	Maximum number of columns to use in the analysis. If x has > max_cols, selected columns are those with the largest number of events.
cores	If larger than 1, use <code>mclapply</code> to run all methods. This is the default. If you use <code>mclapply</code> , MHN and MCCBN should not use OMP (i.e., the number of threads for OMP for MHN and MCCBN should be 1).
paths_max	If TRUE, return all paths to the maxim/maxima, with their probabilities. See details for how they are computed.
mhn_opts	A list with two named arguments. <ul style="list-style-type: none"> • lambda: The penalty for MHN. Defaults to 1/nrow(data). (These are not the lambdas as the estimated parameters for the rates of the continuous-time Markov chains for MHN or CBN or HESBCN.) • omp_threads: Number of OMP threads for MHN. Do not pass thrds > 1 with cores > 1: as with MCCBN, do not use OpenMP threads from forked process from <code>mclapply</code>.
ot_opts	A list with the single named argument <code>with_errors_dist_ot</code> : value for option <code>with.errors</code> in the call to <code>distribution.oncotree</code> . A value of TRUE means to incorporate the false positive and negative errors when returning the probabilities of genotypes under OT. Note that for large models using a value of TRUE can result in very long computing times. Default is TRUE.
cbn_opts	A named list with arguments passed to CBN. <ul style="list-style-type: none"> • omp_threads: OMP threads to be used by CBN (set via the environment variable OMP_NUM_THREADS). Defaults to 1. In contrast to MCCBN and MHN, you can set this to a number larger than one even if you set cores to a number larger than one (i.e., if we use <code>mclapply</code>). It is unclear, though,

	more than 1 thread will speed things much or what is the best number of threads to use; in fact, sometimes it can even slow things down, in particular if you run multiple evams in parallel.
	<ul style="list-style-type: none"> • cbn_init_poset: Initial poset for CBN; one of "linear" or "OT" (default).
hesbcn_opts	Named list of arguments used in the fit of H-ESBCN (details in https://github.com/danro9685/HESBCN).
	<ul style="list-style-type: none"> • MCMC_iter: Number of MCMC iterations to run; this is argument "-n, –number_samples" in the original H-ESBCN C code. Default: 100000, as in the original implementation. Note that the web app uses a larger default of 200000. • reg: Regularization: one of bic (default), aic, loglik. • seed: Seed to run the experiment • silent: Whether to run show message showing the folder name where HESBCN is run
oncobn_opts	Named list of arguments used in the fit of OncoBN. See fitCPN .
mccbn_opts	Named list of arguments used in the fit of MC-CBN. These are model (one of OT-CBN or H-CBN2). The rest are options passed to adaptive.simulated.annealing ; see the help of adaptive.simulated.annealing for details. In addition, the following options:
	<ul style="list-style-type: none"> • tmp_dir: Directory name where the oput is located. This is passed to adaptive.simulated.annealing, as argument outdir, with addname added, if provided. • addname: String to append to the temporary directory name. Default is NULL. • silent: Whether to show a message with the name of the directory where MCCBN is run. This silent is different from mccbn_hcbn2_opts\$verbose.
	Note: do not pass thrds > 1 with cores > 1: as with MHN, do not use OpenMP threads from forked process from mclapply .

Details

Probabilities of evolutionary paths or paths of tumor progression

Details and examples on how probabilities of paths are computed are given in Diaz-Uriarte and Vasallo, 2019 (specifically, see section 3 of file S4_Text, <https://doi.org/10.1371/journal.pcbi.1007246.s006>); see also Hosseini et al., 2019. The models used in those papers all had a single local maximum. Here we follow the same procedure also for models with possibly more than one maximum, such as H-ESBCN. Note that in all cases we assume evolution can only move uphill in fitness and never crosses fitness valleys (which excludes, for example, the scenarios considered in Weinreich and Chao, 2005).

Value

A list with named components (that should be self-explanatory). The pattern is method_component.

- OT_model: Data frame with parent and descendant edges, edge weight, and observed and predicted frequencies of genes.
- OT_f_graph: The fitness graph, as a sparse matrix, with weights obtained from the edge weights (this is not a transition rate matrix). See full documentation for details.
- OT_trans_mat: Transition matrix between genotypes. This is really an abuse of what an untimed OT provides. See full documentation for details.

- OT_predicted_genotype_freqs: Probabilities of genotypes from the OT model, as a data frame.
- OT_paths_max: If paths_max is TRUE, a list of two components, paths and weights. The paths list is a list of igraph.vs (igraph vertex sequences) objects, one for each path; the weights is vector of log-probabilities of each path. If paths_max is FALSE, the default, NA.
- CBN_model: Similar to the ouput from OT, but with lambdas. The lambda to be used is "rerun_lambda".
- CBN_trans_rate_mat: Transition rate matrix as a sparse matrix.
- CBN_trans_mat: Transition matrix between genotypes, obtained from the transition rate matrix using competing exponentials.
- CBN_td_trans_mat: Time-discretized transition matrix, using the uniformization method; see full documentation for details.
- CBN_predicted_genotype_freqs: Named vector of probabilities of genotypes predicted by the CBN model (under a model where sampling times are distributed as an exponential of rate 1).
- CBN_paths_max: As for OT.
- MCCBN_model: As for CBN, only with one column of λ s.
- MCCBN_trans_rate_mat: As for CBN.
- MCCBN_trans_mat: As for CBN.
- MCCBN_td_trans_mat: As for CBN.
- MCCBN_predicted_genotype_freqs: As for CBN.
- MCCBN_paths_max: As for OT.
- MHN_theta: Matrix of estimated thetas (the log-Theta matrix). The values in this matrix can range from minus to plus infinity.
- MHN_trans_rate_mat: As for CBN.
- MHN_trans_mat: As for CBN.
- MHN_td_trans_mat: As for CBN.
- MHN_exp_theta: Matrix of the exponential of thetas; the matrix Θ in Schill et al. (just each theta, exponentiated; not the matrix exponential of the matrix of thetas). These are the multiplicative effects themselves.
- MHN_predicted_genotype_freqs: As for CBN.
- MHN_paths_max: As for OT.
- OncoBN_model: Similar to the ones above (but with a column named theta, instead of lambdas or edge weights), with the additional column dQuoteRelation, that can take values OR (if fitting model DBN) or AND (if fitting model CBN); Single indicates nodes with a single ancestor (where OR or AND make no difference).
- OncoBN_likelihood: Likelihood of the OncoBN model.
- OncoBN_f_graph: As for OT.
- OncoBN_trans_mat: As for OT.
- OncoBN_predicted_genotype_freqs: As for OT.
- OncoBN_fitted_model: DBN or CBN, depending on what you chose.
- OncoBN_epsilon: Epsilon (this is an argument of the call to evam, but it is evaluated after possibly having modified the input data; see below).
- OncoBN_parent_set: .
- OncoBN_paths_max: As for OT.

- HESBCN_model: As for CBN.
- HESBCN_parent_set: As for CBN.
- HESBCN_trans_rate_mat: As for CBN.
- HESBCN_trans_mat: As for CBN.
- HESBCN_td_trans_mat: As for CBN.
- HESBCN_predicted_genotype_freqs: As for CBN.
- HESBCN_paths_max: As for OT.
- original_data: The original data.
- analyzed_data: The data that were actually analyzed. Can differ from the original data because of the data pre-processing steps.
- genotype_id_ordered: A named vector, from 1:number of genotypes, with names the genotypes. This can be useful for sorting; WT has value 1, and genotypes are ordered by increasing number of mutations and, withing number of mutations, alphanumerically.
- all_options: All of the options used, as a list of lists.

Note

For some methods, such as MHN and OncoBN, some parameters tipically depend on the data (lambda and epsilon for MHN and OncoBN, respectively). Since we first examine and possibly modify the input data, the values might not be the ones you thought you entered, as the **options should be evaluated after the data are pre-processed**.

The **data pre-processing** involves, in sequence, these steps:

- Adding pseudosamples: If any gene (column) is always observed mutated (i.e, has a value of 1 for all observations), we add one observation that has no gene mutated.
- Removing genes with no mutations: Any column that has value of 0 for all observations is removed.
- Merging identical columns: Any identical columns are replaced by a single one (with a new identifier, the result of pasting the names of the fused columns separated by a _).
- No more than max_cols: If the “max_cols” argument is not NULL, and if the data set has more columns than max_cols, we keep only max_cols columns of data, those with the largest number of mutations.

Changing only some options: Often, you will want to change only some of the options. You can enter, in the list, only the options you want changed (not the remaining ones). There is one example below.

During the execution, and as messages, the elapsed time of each procedure is reported. This includes executing the model itself and possible additional operations, such as obtaining the transition rate matrix, etc. (So, for example, the time for estimating the matrix of thetas for MHN is much smaller than the reported time here, which also includes building the transition rate matrix).

By default, we do not return paths to maximum/maxima, as their number can grow very quickly with number of genotypes and you only need them if, well, you care about them.

evamtools-deprecated *Deprecated functions in package ‘evamtools’*

Description

These functions are provided for compatibility with older versions of ‘evamtools’ only, and will be defunct at the next release.

Details

The following functions are deprecated and will be made defunct; use the replacement indicated below:

- plot_CPMs: [plot_evam](#)
- sample_CPMs: [sample_evam](#)

every_which_way_data *Cancer data sets from Diaz-Uriarte and Vasallo, 2019; also used in Diaz-Colunga and Diaz-Uriarte, 2021.*

Description

Twenty two cancer data sets used in Diaz-Uriarte and Vasallo, 2019, as well as Diaz-Colunga and Diaz-Uriarte, 2021. The data cover six different cancer types (breast, glioblastoma, lung, ovarian, colorectal, and pancreatic cancer), use different types of features (nonsynonymous somatic mutations, copy number alterations, or both) were analyzed in terms of pathways, functional modules, genes, gene events, or mutations (yielding from 3 to 192 different features), and have samples sizes from 27 to 594.

The original sources are listed below. Most of these data sets have been used before in CPM research.

Complete details about sources, processing, and former use in CPM papers are available from S5 Text (<https://doi.org/10.1371/journal.pcbi.1007246.s007>) of Diaz-Uriarte and Vasallo, 2019.

Usage

```
data("every_which_way_data")
```

Format

A list of length 22. Each element of the list is a data set, with subjects in rows and genes/probes in columns.

ex_mixed_and_or_xor *Small example data set that shows, for HESBCN, both AND and OR, or AND and XOR, in some runs.*

Description

Synthetic data set used for testing and plotting. HESBCN, with some seeds, will infer both AND and OR, or AND and XOR, or the three of them.

Usage

```
data("ex_mixed_and_or_xor")
```

Format

A data frame with “genes” in columns and “patients” in rows.

Examples

```
data("ex_mixed_and_or_xor")

out_AND_OR_XOR <- evam(ex_mixed_and_or_xor,
                         methods = c("OT", "HESBCN", "MHN", "OncoBN"),
                         hesbcn_opts = list(seed = 26))

plot_evam(out_AND_OR_XOR, plot_type = "trans_mat", top_paths = 4)
```

examples_csd	<i>Cross sectional data sets</i>
--------------	----------------------------------

Description

A list of cross sectional data set to be used as example inputs, for instance by the Shiny web app. This file was generated by running the script /inst/miscell/examples/toy_datasets.R

Usage

```
data(examples_csd)
```

Format

A list of cross sectional data sets. Each data set includes 1) the data and 2) a name. In some cases there is also dag, or the values of a matrix. A list with 3 items:

csd csd, created by directly entering cross-sectional data.

dag dag, from models with DAGs.

matrix matrix, from MHN.

plot_evam	<i>Plot results from EvAMs (CPMs)</i>
-----------	---------------------------------------

Description

Plots fitted EvAMs (CPMs), both fitted model and custom plots for transition rates and transition probabilities.

Usage

```
plot_evam(  
  cpm_output,  
  samples = NULL,  
  orientation = "horizontal",  
  methods = NULL,  
  plot_type = "trans_mat",  
  label_type = "genotype",  
  fixed_vertex_size = FALSE,  
  top_paths = NULL  
)  
  
plot_CPMs(  
  cpm_output,  
  samples = NULL,  
  orientation = "horizontal",  
  methods = NULL,  
  plot_type = "trans_mat",  
  label_type = "genotype",
```

```

fixed_vertex_size = FALSE,
top_paths = NULL
)

```

Arguments

<code>cpm_output</code>	Output from the cpm
<code>samples</code>	Output from a call to sample_evam . Necessary if you request plot type <code>transitions</code> .
<code>orientation</code>	String. If it is not "vertical" it will be displayed with an horizontal layout. Optional.
<code>methods</code>	Vector of strings with the names of methods that we want to plot. If <code>NULL</code> , all methods with output in <code>cpm_output</code> . The list of available methods is OT, OncoBN, CBN, MCCBN, MHN, HESBCN.
<code>plot_type</code>	One of: <ul style="list-style-type: none"> • <code>trans_mat</code>: Transition matrix between genotypes (see supporting information for OT and OncoBN). This plots the object of name <code>trans_mat</code> from the output of evam. • <code>trans_rate_mat</code>: Transition rate matrix between genotypes; unavailable for OT and OncoBN. This plots the object of name <code>trans_rate_mat</code> from the output of evam. • <code>obs_genotype_transitions</code>: Observed transitions during the simulation of the sampling process. This plots the object called <code>obs_genotype_transitions</code> from the output of sample_evam.
<code>label_type</code>	Type of label to show. One of: <ul style="list-style-type: none"> • <code>genotype</code>: Displays all genes mutated • <code>acquisition</code>: Only displays the last gene mutated
<code>fixed_vertex_size</code>	Boolean. If <code>TRUE</code> , all nodes have the same size; otherwise, scale them proportional to frequencies of observed data.
<code>top_paths</code>	Number of most relevant paths to plot. Default <code>NULL</code> will plot all paths. See below, Description, for details about relevance. With many genes, and particularly for MHN (or other methods, when there are no restrictions in the order of accumulation of mutations), using <code>NULL</code> can lead to a very long time to plot.

Value

By default this function creates a top row with the DAG of the CPM or the log-Theta matrix for MHN. The bottom row has a custom plot for the transition matrix, or the transition rate matrix, or the observed genotype transitions.

In the bottom row plots, unless `fixed_vertex_size = TRUE`, the size of genotype nodes is proportional to the observed frequency of genotypes for all plots except for `plot_type = 'obs_genotype_transitions'`, where it is proportional to the genotype frequency as obtained by the sampling from the predictions of each method; if a node (genotype) has no observations, its size is of fixed size. Thus, for all plots except `plot_type = 'obs_genotype_transitions'` the size of the genotype nodes is the same among methods, but the size of the genotype nodes can differ between methods for `plot_type = 'obs_genotype_transitions'`.

In the top plots, in the DAGs, when a node has two or more incoming edges, color depends on the type of relationship. (With a single incoming edge, there is no difference in model behavior with

type of edge and, for consistency with OT and CBN, nodes with a Single parent have edges colored the same way as nodes with two or more parents and AND relationship).

In the bottom row plots, non-observed genotypes are shown in light green, to differentiate them from the observed genotypes (shown in orange).

Note

The color and design of figures in the bottom row, depicting transition matrices, transition rate matrices, and observed genotype transitions are heavily inspired by (a blatant copy of) some of the representations in Greenbury et al., 2020.

It is easy to get the plots to display poorly (overlapping names in nodes, overlapping labels between plots, etc) if you use long gene names. For best results, try to use short gene names.

The criteria to decide which are the most relevant paths with the top_paths option is the following:
 1) Get all the leaves from the graph. 2) Calculate all the paths leading from "WT" to all leaves.
 3) Select n paths with highest cumulative weighted sum. The weights used depend on the type of plot (plot_type): for trans_mat it will be log probabilities (so the most relevant paths are the most likely paths), for trans_rate_mat it will be rates, and for obs_genotype_transitions it will be raw counts.

Plots can be more readable with a combination of top_paths and label_type. If label_type = 'acquisition' node labels will disappear and edge label will be shown instead. They will display the information of the last gene mutated.

plot_CPMs has been deprecated. Use plot_evam.

```

random_evam	<i>Generate a random EvAM model.</i>
-------------	--------------------------------------

Description

Generate random EvAM (CPM) models.

Usage

```
random_evam(ngenes = NULL,
            gene_names = NULL,
            model = c("OT", "CBN", "HESBCN",
                      "MHN", "OncoBN"),
            graph_density = 0.35,
            cbn_hesbcn_lambda_min = 1/3,
            cbn_hesbcn_lambda_max = 3,
            hesbcn_probs = c("AND" = 1/3,
                            "OR" = 1/3,
                            "XOR" = 1/3),
            ot_oncobsn_weight_min = 0,
            ot_oncobsn_weight_max = 1,
            ot_oncobsn_epos = 0.1,
            oncobsn_model = "DBN"
            )
```

Arguments

ngenes	Number of genes in the model. Specify this or gene_names.
gene_names	Gene names.Specify this or ngenes.
model	One of OT, CBN, OncoBN, MHN, HESBCN.
graph_density	Expected number of non-entries in the adjacency matrix (all methods expect MHN) or the theta matrix (MHN). See details.
cbn_hesbcn_lambda_min	Smallest value of lambda for CBN and HESBCN.
cbn_hesbcn_lambda_max	Largest value of lambada for CBN and HESBCN.
hesbcn_probs	For nodes with more than one ancestor, the probability that the dependencies are AND, OR, XOR. You must pass a named vector.
ot_oncobsn_weight_min	Smallest possible value of the weight or theta for OT and OncoBN respectively.
ot_oncobsn_weight_max	Largest possible value of the weight or theta for OT and OncoBN respectively.= 1,
ot_oncobsn_epos	epsilon (OncoBN) or epos (OT) error.
oncobsn_model	One of "DBN" or "CBN".

Details

The purpose of this function is to allow easy simulation of data under a specific model. Details follow for specific models, with explanation of parameters.

For MHN we use the same procedure as available in the original code of Schill et al. `graph_density` is $1 - \text{sparsity}$. A matrix of random thetas (from a normal 0, 1, distribution) is generated, where the number of non-zero entries is controlled by `graph_density`.

For CBN a random poset is generated by calling `random_poset` in the `mccbn` package (function exported but not documented) and generating random lambdas uniformly distributed between `cbn_hesbcn_lambda_min` and `cbn_hesbcn_lambda_max`. No specific provision is made for randomly generating from MCCBN, as the way to simulate is similar to CBN (but see also the additional documentation for details about the error models).

For H-ESBCN we follow a similar procedure as for CBN, but nodes that have two or more parents are then assigned, at random, a relationship that can be AND, OR, or XOR, as given by `hesbcn_probs`.

For OT we use a procedure similar to the one for CBN, but edge weights are uniformly distributed between `ot_oncobn_weight_min` and `ot_oncobn_weight_max`. Since under OT a node can have only one parent, for all nodes that have two or more parents, we randomly keep one of the parents. Thus, `graph_density` is often larger than the actual number of non-zero connections in the adjacency matrix.

For OncoBN we do as for CBN. If you specify `oncobn_model` to be DBN, all dependencies on two or more parents are OR dependencies; if you specify CBN, dependencies are AND dependencies. As for OT, thetas are uniformly distributed between `ot_oncobn_weight_min` and `ot_oncobn_weight_max`.

For both OT and OncoBN model, `ot_oncobn_epos` controls the probability that a gene can mutate if its requirements are not satisfied. (This is thus intrinsic to the model, and independent of observation error; see next).

In all cases, the predicted distribution of genotypes for a model is done assuming perfect compliance with the model. See the additional documentation for details about the error models. Adding observation error can be done using `obs_error > 0` when calling [sample_evam](#).

Value

Random model, with the same structure as returned by function [evam](#). Thus, a named list with all the returned entries from [evam](#) for a given method.

See Also

[sample_evam](#)

Examples

```
rmhn <- random_evam(model = "MHN", ngenes = 5)
rcbn <- random_evam(model = "CBN", ngenes = 5,
                      graph_density = 0.5)

## Now, obtain some data
## You can obtain a random sample, with counts of frequencies of
## genotypes and add observation noise
sample_mhn <- sample_evam(rmhn, N = 1000, obs_noise = 0.05)

## The component sampled_genotype_counts_as_data is
## a matrix that you can then pass to evam as the
```

```
## input data argument (x)
```

runShiny*Run the web application of evamtools***Description**

Launch the server with the web based app.

Usage

```
runShiny(host="0.0.0.0", port=3000, test.mode = FALSE)
```

Arguments

host	Host where the app will be listening
port	Port where the app will be listening
test.mode	See runApp

sample_ebam*Obtain samples of genotypes from the EvAM (CPM) models and, optionally, counts of genotype transitions.***Description**

Obtain samples of genotypes from the CPM models and, optionally, counts of genotype transitions.

For OT and OncoBN we always obtain the absolute genotype frequencies by drawing samples of size N, with replacement, using as probabilities the predicted genotype frequencies.

For the remaining methods, that is also what we do, unless you request also obs_genotype_transitions and state_counts. In this case, since we need to simulate sampling from the continuous-time Markov Chain (with transition rates given by the transition rate matrix) to obtain state counts and observed genotype transitions, we use this same sampling to obtain the absolute genotype frequencies. (The results are, of course, equivalent, but sampling directly from the predicted frequencies is much faster). Note that the option to request obs_genotype_transitions was removed from the web app, as it was rarely used, but lead to confusion and could increase without good reason running times. So, from the web app, we sample without using obs_genotype_transitions.

Observed genotype transitions, if requested, are obtained by counting the transitions between pairs of genotypes when simulating from the continuous-time Markov Chain. State counts are also obtained by counting from this process how many times a genotype was visited.

Usage

```
sample_evam(cpm_output, N,
            methods = NULL,
            output = c("sampled_genotype_counts"),
            obs_noise = 0,
            genotype_freqs_as_data = TRUE
        )

sample_CPMs(cpm_output, N,
            methods = NULL,
            output = c("sampled_genotype_counts"),
            obs_noise = 0,
            genotype_freqs_as_data = TRUE
        )
```

Arguments

<code>cpm_output</code>	Output from calling <code>all_methods2trans_mat</code>
<code>N</code>	Number of samples to generate
<code>methods</code>	Vector of strings with the names of methods that we want to sample. If <code>NULL</code> , all methods with output in <code>cpm_output</code> . The list of available methods is OT, OncoBN, CBN, MCCBN, MHN, HESBCN.
<code>output</code>	A vector with one or more of the following possible outputs: <code>sampled_genotype_counts</code> , <code>obs_genotype_transitions</code> , <code>state_counts</code> . Even if requested, <code>obs_genotype_transitions</code> and <code>state_counts</code> are not available for OT and OncoBN.
<code>obs_noise</code>	When obtaining a sample, should we add observation noise (for example, genotyping error) to the data? If larger than 0, this <code>obs_noise</code> proportion of entries in the sampled matrix will be flipped (i.e., 0s turned to 1s and 1s turned to 0s).
<code>genotype_freqs_as_data</code>	If <code>TRUE</code> , return a matrix where each row is a "sampled genotype", where 0 denotes no alteration and 1 alteration in the gene of the corresponding column.

Value

A list, with a many entries as methods times number of components requested. For each method among CBN, MCCBN, HESBCN, and MHN:

- `sampled_genotype_counts`: Counts, or absolute genotype frequencies, obtained by sampling from the predicted frequencies. See also Description, below.
- `obs_genotype_transitions`: Number of observed transitions between genotypes (as a sparse matrix).
- `state_counts`: Number of times each genotype was visited during the transitions. Column sums of observed genotype transitions are equal to state counts.
- `sampled_genotype_counts_as_data`: The genotypes in a matrix of 0/1. This can directly be passed as an argument for `evam`, as the input data.

Observed genotype transitions are not the way to obtain estimates of transition probabilities. The transition probabilities given by each method are already available from the output of `evam` itself. These genotype transitions are the observed transitions during the simulation of the sampling process and, thus, have additional noise.

For OT and OncoBN, only the `sampled_genotype_counts` and `sampled_genotype_counts_as_data` components are available (the other two are not available).

Note

sample_CPMs has been deprecated. Use sample_exam.

SHINY_DEFAULTS

*Defaults options for running the shiny web app***Description**

Defaults of the web app. This file was generated by running the script /inst/shiny-examples/evamtools/DEFAULTS.R
 You will want to rerun it (so that the RData file is created again) whenever you make changes to it.
 The object is called .ev_SHINY_df1t to minimize the risk of overwriting.

Usage

```
data(SHINY_DEFAULTS)
```

Format

Defaults values of the shiny app

max_genes Maximun number of genes allowed

min_genes Minimum number of genes allowed

ngenes Integer of default number of genes to use when building

cpm_samples Number of patients to samples to generate csd data from a matrix using with CPM outputs

all_cpms All CPMs in evamtools

csd_samples Number of patients to samples to generate csd data from a matrix or a dag

template_data One of:

- csd_counts:Data frame with the counts of each genotype
- data:Data frame with cross sectional data.
- dag:Matrix of 10x10 with lambdas
- dag_parent_sest>List of 10 elements with "Single"
- lambdas:Vector of 10 lambdas, equals to 1
- thetas:Matrix of 10x10 with thetas
- gene_names>List with gene names
- name:String with the data set name

1 Introduction

Here I explain how we can use OncoSimulR¹ to get accessible genotypes and transition matrices for CBN (and MCCBN), OT, HESBCN, and OncoBN. The code for using OncoSimulR is implemented in `access_genots_from_oncosimul.R`.

(This document is written, on purpose, using an itemized list style, with plenty of repetition and detailed examples, to make it suitable for instance for class use.)

¹A BioConductor package for forward population genetic simulation in asexual populations; it allows us to specify fitness, among other ways, using DAGs of restrictions. Repo at <https://github.com/rdiaz02/OncoSimul>. Citation: Diaz-Uriarte, R. (2017). OncoSimulR: Genetic simulation with arbitrary epistasis and mutator genes in asexual populations. Bioinformatics, 33(12), 1898–1899. <https://doi.org/10.1093/bioinformatics/btx077>.

2 Using OncoSimulR to get accessible genotypes and transition matrices

OncoSimulR has had, for a long time, the AND, XOR, OR operations (see the help of "allFitnessEffects", under "typeDep"), if a gene depends on other genes with the same relationship for all parents. Since we can obtain the fitness of genotypes, obtaining accessible genotypes is simple:

- Use an appropriate setting for the "s"
- Use $-\infty$ for sh (so if restrictions are not satisfied, a genotype has fitness 0).
- Evaluate the fitness of genotypes.
- Call function "genots_2_fgraph_and_trans_mat".
 - This is a general function, not linked to any specific cancer progression model. In other words, given a fitness landscape (a mapping from genotypes to fitness) find the accessible genotypes and the transition matrices (not transition rate matrices) between genotypes.
 - For example, this procedure does not assume that mutations that do not kill a genotype always increase fitness or at least do not decrease it. A mutation might increase fitness in some contexts (with some other mutations) and decrease in other contexts, such as with sign and reciprocal sign epistasis.
 - This procedure **assumes SSWM (strong selection, weak mutation)**. Moreover, **we assume evolution can only move uphill in fitness**. For example, a genotype is considered not accessible if its fitness is less than, or equal to (note the “or equal to”) that of its immediate ancestor, and we cannot cross fitness valleys².
 - This function returns accessible genotypes, fitness graph, and transition matrices directly from the fitness of the genotypes.

2.1 Computing fitness of genotypes: for CBN (and MCCBN) and OT

- OncoSimulR, when using DAGs, uses a model of fitness (birth rate), for a genotype with restrictions satisfied as $\Pi(1 + s_i)$.
 - Again, to emphasize the above: s_i , when using OncoSimulR with a DAG, is the selection coefficient from gene i **with its restrictions satisfied**.
- Recall that for CBN the transition probabilities can be computed from competing exponentials. For example, suppose from genotype A we can go to genotypes AB and AC. The probability of going to AB should be $\lambda_B / (\lambda_B + \lambda_C)$.
- As in p. 7 of the supplementary material of Weinreich et al., 2006, (Weinreich, D. M., Delaney, N. F., DePristo, M. A., & Hartl, D. L. (2006). Darwinian Evolution Can Follow Only Very Few Mutational Paths to Fitter Proteins. *Science*, 312(5770), 111–114.<https://dx.doi.org/10.1126/science.1123539>), let us define the selective coefficient of a mutation i as the relative fitness difference that it causes along the mutational pathway.

²This excludes, for example, the scenarios studied in Weinreich, D. M., & Chao, L. (2005). Rapid evolutionary escape by large populations from local fitness peaks is likely in nature. *Evolution; international journal of organic evolution*, 59(6), 1175–1182. <http://dx.doi.org/10.1111/j.0014-3820.2005.tb01769.x> .

- $W_{AB} = W_A (1 + s_B)$ or $s_B = \frac{W_{AB} - W_A}{W_A}$.
 - Using our previous example, $Pr(A \rightarrow AB) = \frac{W_{AB} - W_A}{(W_{AB} - W_A) + (W_{AC} - W_A)}$, where W_x is fitness of genotype x .
 - Thus, we get from the above $Pr(A \rightarrow AB) = \frac{s_B}{s_B + s_C}$.
 - (We wrote $W_{AB} = W_A (1 + s_B)$. This we can do as we explained what the meaning of the s_i are: selection coefficient from gene i with its restrictions satisfied. See below: [Transition probabilities using an epistatic specification](#).)
- Note that this is the same procedure as in Weinreich et al., 2006, (Weinreich, D. M., Delaney, N. F., DePristo, M. A., & Hartl, D. L. (2006). Darwinian Evolution Can Follow Only Very Few Mutational Paths to Fitter Proteins. *Science*, 312(5770), 111–114. <https://dx.doi.org/10.1126/science.1123539>) supplementary material, p. 4): $s_{i \rightarrow j}$ "the selection coefficient for the mutation that carries allele i to allele j "³.
 - Specifically, see equation S5b in the supplementary material of Weinreich et al., 2006, which shows the relationship between the expected value of the conditioned probability of fixation in a mutation from i to j and the expected value of the ratio of the selection coefficient for the mutation that turns i to j over the sum of selection coefficients of beneficial mutations that turn i into all other alleles; see also their figure S1 in p. 7 of the supplementary material that shows the accuracy of their expression.
 - Note that this is similar to what is done in Hosseini et al., 2019 (Hosseini, S., Diaz-Uriarte, Ramon, Markowetz, F., & Beerenwinkel, N. (2019). Estimating the predictability of cancer evolution. *Bioinformatics*, 35(14), 389–397. <https://dx.doi.org/10.1093/bioinformatics/btz332>), p. i392. The difference is that in Hosseini et al. the s_i is defined as the fitness difference, not the relative fitness difference (and in Hosseini et al there is a normalizing constant, as given by eq. 8).
 - Additional note: In Gerstung et al., 2011 (Gerstung, M., Eriksson, N., Lin, J., Vogelstein, B., & Beerenwinkel, N. (2011). The Temporal Order of Genetic and Pathway Alterations in Tumorigenesis. *PLoS ONE*, 6(11), 27136. <https://dx.doi.org/10.1371/journal.pone.0027136>), PLoS ONE (p.8) the relationship between λ_i and s_i is also discussed, with additional references given.
 - So when using OncoSimulR we do as follows:
 - Set $s_i = \lambda_i$ (for OT, we use edgeWeight instead of λ).
 - Obtain the fitness of all genotypes from OncoSimulR.
 - If so desired (e.g., to ensure the maximum fitness is a specific number), scale all fitnesses by the appropriate factor (that also ensures that WT is kept at one; see, for instance, function `scale_fitness_2` in file `access_genots_from_oncosimul.R`).
 - Is the above correct for OT? Strictly not as OT are untimed oncogenetic trees. (And, yes, we are aware that under OT if you have, say, both A and B descend from root, the probability of genotype A is $p_a(1 - p_b)$).
 - It is important to emphasize that we are not claiming λ_i should be taken as equal to s_i . We are using this procedure to obtain accessible genotypes and transition probabilities

³Selection coefficient has the usual textbook definition. For example, Gillespie, 2004 (Population genetics: a concise guide, 2nd. Baltimore, Md: The Johns Hopkins University Press.), p. 63. But here we write $W_{AB} = W_A (1 + s_B)$, and thus if $s_B > 0$ AB is fitter than A; see also p.7 of the supplementary material of Weinreich et al., 2006

between genotypes, but not transition rate matrices. For example, as mentioned above, multiplying all s_i by the same constant leaves these transition probabilities unchanged⁴. But even if multiples of the λ_i result in the same transition probabilities, the transition rate matrices are different (the evolutionary process is faster or slower).

2.2 Crucial assumption above

- We compute fitness above assuming that only one of two things can happen: a mutation provides a fitness benefit or it leads to death. When the requirements are satisfied, a mutation conveys a fitness increase (λ_i); otherwise, the cell with the mutation has fitness 0.
- Strictly, mutations without dependencies satisfied might not be lethal, but they should not confer any fitness advantage, so that we will not observe them become fixated in the population (Gerstung et al., 2009, p. 2810: "(...) mutations that need to be present before mutation i can fixate.". Gerstung and Beerenwinkel, 2010, Waiting time models of cancer progression. Mathematical Population Studies, 17, 115–135; p. 126: "with steps including both mutation and clonal expansion occurring at effective rates λ_j ". Beerenwinkel, N., & Sullivant, S. (2009). Markov models for accumulating mutations. Biometrika, 96(3), 645, p. 659: "In an evolutionary process, this waiting time includes the generation of the mutation plus the time it takes for the allele to reach fixation in the population" and p. 660 "The parameters λ correspond to the rate of evolution, i.e. the product of population size, mutation rate and fixation probability").
- In OncoSimulR, in addition to the s_i , it is possible to set $sh = 0$, meaning there is no penalty for not respecting the restrictions. When $sh = 0$ there is also no fitness gain, either, so fitness for those genotypes ends up being the fitness of the immediate parent (there is no contribution from the gen without restrictions satisfied to the fitness of the parent genotype). Regardless, when $sh = 0$, the transition matrix does not change compared to the transition matrix we obtain if we assume that mutations to genotypes with non-satisfied dependencies lead to a fitness of 0: we said above that a genotype is considered not accessible if its fitness is less than, or equal to (note the "or equal to") that of its immediate ancestor.
- To elaborate on this point: The output from the code, with $sh = 0$, will result in more genotypes being shown as accessible. It is arguable, though, that those genotypes are not really accessible, since their fitness is never larger than the fitness of their ancestor. So the probability of transitioning to them will be 0 under the expressions above when in SSWM. We have changed the code so that now something is only shown as accessible if its fitness is strictly larger than the fitness of its ancestor.
- (Actually, in OncoSimulR, the s_h can vary by gene, so we could have different s_{hi} , but this does not affect these arguments).

2.3 Fitness specification with OncoSimulR: DAGs vs. epistatic fitness specifications

- We said above: "Again, to emphasize the above: s_i , when using OncoSimulR with a DAG, is the selection coefficient from gene i **with its restrictions satisfied**."

⁴We can scale all fitness with a function like $W^* = 1 + (W - 1) \alpha$.
 $W_A = 1 + s_A$. $W_A^* = 1 + s_A^*$. Thus $s_A^* = (W_A - 1) \alpha = s_A \alpha$.

- This also means, when using DAGs in OncoSimulR, that terms such as s_{ij} are not used in that specification: they are not needed as the DAG models do not include epistasis beyond that given by the DAG, and all these epistatic interactions we capture with the DAG and the s_i and s_h , which denote the fitness effects when restrictions are satisfied and not satisfied, respectively.
- But with OncoSimulR you can also specify fitness with the usual multiplicative expression where you specify explicitly the contribution of genes and gene interactions (e.g., s_{ij} for the effect of the interaction between genes i and j , so that fitness of the genotype with both i and j mutated would be $(1 + s_i)(1 + s_j)(1 + s_{ij})$).
- In other words, suppose j depends on i . The usual epistatic interaction fitness specification would write: $W_{ij} = (1 + s_i)(1 + s_j)(1 + s_{ij})$ and $W_j = (1 + s_j)$.
- Using the DAG, if the restriction is not satisfied, i.e., for genotype with only j : $W_j = (1 + s_h)$. If the restriction is satisfied, $W_{ij} = (1 + s_i)(1 + s_j)$. So the meaning of the s is different.
- To fully elaborate here, and to give a more complex example, suppose C depends on both A and B, according to the DAG.
 - When using the DAG, then, these are the expressions for some genotypes:
 - * $W_{ABC} = (1 + s_A)(1 + s_B)(1 + s_C)$
 - * $W_{AC} = (1 + s_A)(1 + s_h)$
 - * (If we had gene-specific s_h , such as s_{hC} , that does not change anything fundamental, just adds a subscript)
 - If we were to use an epistatic specification:
 - * $W_{ABC} = (1 + s_A)(1 + s_B)(1 + s_C)(1 + s_{AB})(1 + s_{AC})(1 + s_{BC})(1 + s_{ABC})$
 - * $W_{AC} = (1 + s_A)(1 + s_C)(1 + s_{AC})$
- Therefore, the meaning of the s_i is not the same under both specifications. That is why we said " s_i , when using OncoSimulR with a DAG, is the selection coefficient from gene i **with its restrictions satisfied.**" and "terms such as s_{ij} are not used in that specification: they are not needed as the DAG models do not include epistasis beyond that given by the DAG, and all these epistatic interactions we capture (...)".
- Yes, sure, we could always re-write the s_i and s_{hi} in the DAG specification as a function of the s_i, s_{ij}, s_{ijk} in the epistatic specification. (See section [Transition probabilities using an epistatic specification](#)).
- This was just for the sake of completeness. The use of s_h and the epistatic fitness specification is fully explained in the documentation of OncoSimulR and its vignette, and is not in the scope of this document.

2.4 Transition probabilities using an epistatic specification

- Suppose B and C both depend on A. If we were to use an specification with epistasis, instead of how we have used and interpreted the s_i using the DAGs, then we would have to write $W_{AB} = W_A(1 + s_B^*)(1 + s_{AB}^*)$, where now I am using s^* to make the sets of s clearly distinct. We can express the s_B as a function of s_B^* and s_{AB}^* . If we set $s_B^* = 0$ (similar to setting $sh = 0$) then $s_B = s_{AB}^*$. Otherwise, the expression will be $s_B = ((1 + s_B^*)(1 + s_{AB}^*)) - 1$; and, to respect the restrictions, it must be the case that $s_B^* < 0$.

- The expressions for probabilities of transition become messier, but you end up with a ratio of

$$\frac{\text{increase_in_fitness_from_acquiring_B}}{\text{increase_in_fitness_from_acquiring_B} + \text{increase_in_fitness_from_acquiring_C}}$$

where *increase_in_fitness_from_acquiring_B* would include the effect of B, s_B^* , and the epistatic interaction, s_{AB}^* .

- s_B is still the relative fitness difference $\frac{W_{AB}-W_A}{W_A}$. Which is the same as saying that $((1+s_B^*)(1+s_{AB}^*)) - 1 = \frac{W_{AB}-W_A}{W_A}$ is the relative fitness difference.
- This shows we can directly use the DAG fitness specification where we take the s_i as the selection coefficient from gene i with its restrictions satisfied.
- And why do we do what we do with CBN? Because it simplifies everything and fitness can be written as $\prod(1+s_i)$ for any genotype with its restrictions satisfied.
 - If neither A nor B depend on anything, then the expression for fitness is $(1+s_A)(1+s_B)$ because, under CBN, there is no epistasis here so $s_{AB} = 0$ (look, for example, at the transition rate matrix in Montazeri et al., 2016, Figure 1, for the transition from genotype 1 to genotype 1,2 or from genotype 2 to genotype 1,2).
 - If B depends on A, when we consider the transition from A to B, we can use a single term, $(1+s_X)$ to multiply $(1+s_A)$, and that $s_X = \lambda_B$. That λ_B is the (relative) increase in fitness due to B, when B's restrictions are satisfied (for example, in Example 1 in Montazeri et al., 2016 (Large-scale inference of conjunctive Bayesian networks. Bioinformatics, 32(17), 727–735. <https://dx.doi.org/10.1093/bioinformatics/btw459>), see the transition rate matrix from genotype 2 to genotype 2,4⁵). You can think of this s_X as the joint combination of the effect of B on its own and the epistasis of A and B; but thinking of B on its own is a moot point, since B on its own (i.e., without A, without its restrictions satisfied) is not a genotype that can be observed.
 - Thus, for any genotype, do $\prod(1+s_i)$, where $s_i = \lambda_i$ when the restrictions are satisfied.

2.4.1 Another example about the relationship between s , λ , s_h

- Remember that having $\lambda_i < 0$ makes no sense.
- Suppose a model where A and B depend on no one, D depends on A and C depends on both A and B.
- Simple case:
 - $W_{AD} = (1+\lambda_A)(1+s_D)(1+s_{AD})$
 - $W_{AD} = (1+\lambda_A)(1+\lambda_D)$
 - So: $1+s_{AD} = \frac{1+\lambda_D}{1+s_D}$
 - If $s_D = 0$ we get the $s_{AD} = \lambda_D$ or "the epistatic term is equal to the lambda".
 - If $s_D < 0$ then the epistatic term, $s_{AD} > \lambda_D$: it has to be large enough to compensate for the decrease in fitness from the single D.

⁵Notice that Figure 1 is correct, but the matrix in Example 1 has a typo, and is missing the entry for λ_4 ; or look at the transition from 1,2 to 1,2,3 and 1,2,4

- This can matter if we try to generate $s_{xy\dots}$ from some distribution and match them to the λ .
- Beware, though, of a simple interpretation of the s_D as s_h , specially when there are more genes. An example:
 - $W_{ADC} = (1 + \lambda_A)(1 + s_D)(1 + s_{AD})(1 + s_C)(1 + s_{DC})(1 + s_{AC})(1 + s_{ACD})$
 - But we can replace the second and third terms:
 - * $W_{ADC} = (1 + \lambda_A)(1 + \lambda_D)(1 + s_C)(1 + s_{DC})(1 + s_{AC})(1 + s_{ACD})$
 - OncoSimulR is NOT replacing all the extra terms by s_h .
 - * If it did you would get:
 - $W_{ADC} = (1 + \lambda_A)(1 + \lambda_D)(1 + s_h)^4$
 - * But what OncoSimul actually gives you is:
 - $W_{ADC} = (1 + \lambda_A)(1 + \lambda_D)(1 + s_h)$
 - * Why? Because only one gene, C, has not got its restrictions satisfied.
 - * In other words, the number of $(1 + s_h)$ is equal to the number of genes (not genes and gene combinations) with their restrictions not satisfied.
 - In particular, note that this is not correct:
 - * $W_{ADC} = (1 + \lambda_A)(1 + s_h)(1 + s_{AD})(1 + s_h)(1 + s_h)(1 + s_h)(1 + s_h)$
 - * Where the first s_h would correspond to s_D and the rest to C, AC, DC, ACD.
 - * And thus, it is not correct to write: $1 + s_{AD} = \frac{1+\lambda_D}{1+s_h}$
 - Of course, if $s_h < 0$ then $W_{ADC} < W_{AD}$.

- And with this same DAG, we can write either:
 - $W_{ABC} = (1 + \lambda_A)(1 + \lambda_B)(1 + \lambda_C)$
 - $W_{ABC} = (1 + \lambda_A)(1 + \lambda_B)(1 + s_C)(1 + s_{AC})(1 + s_{BC})(1 + s_{ABC})$
 - As before we could do: $(1 + s_{ABC}) = \frac{1+\lambda_C}{(1+s_C)(1+s_{AC})(1+s_{BC})}$
 - And this shows again that the epistatic term for ABC (i.e., when restrictions are satisfied) might have to be very large to compensate for large negative fitness effects of mutations without restrictions satisfied (e.g., s_C).

3 What about H-ESBCN/PMCE, with AND, XOR, OR?

By H-ESBCN/PMCE I mean the method described in

- Angaroni, F., Chen, K., Damiani, C., Caravagna, G., Graudenzi, A., & Ramazzotti, D. (2021). PMCE: efficient inference of expressive models of cancer evolution with high prognostic power. *Bioinformatics*, 38(3), 754–762. <http://dx.doi.org/10.1093/bioinformatics/btab717>

We can repeat what we did above, with OR and XOR replaced by, well, OR and XOR in OncoSimulR (OR and XOR are also called SM and XMPN in OncoSimulR). OncoSimulR has dealt with OR, XOR, AND, and mixtures of them since many years ago. Remember also that in the H-ESBCN model if a gene depends on a set of genes, it has the same type of dependency on all the genes of that set.

4 OncoBN

What about OncoBN, the method described in Nicol, P. B., Coombes, K. R., Deaver, C., Chkrebtii, O., Paul, S., Toland, A. E., & Asiaee, A. (2021). Oncogenetic network estimation with disjunctive Bayesian networks. Computational and Systems Oncology, 1(2), 1027. <http://dx.doi.org/10.1002/cso2.1027>

OncoBN can fit both conjunctive (AND) and disjunctive (OR, not XOR) models; for the first you specify `model = "CBN"` and for the second `model = "DBN"`. So it resembles CBN and HESBCN. However, the θ s returned by OncoBN are not rates, as in CBN, HESBCN, or MHN, but rather probabilities of seeing specific alterations at the time of observation as in OT. So probably a better way to think of OncoBN is as an extension of OT, where nodes can have multiple parents, and the relationship of dependence can be AND or OR (but not both).

We deal with OncoBN as with any other method, but as we do with OT, we do not interpret the parameters as rates. This also means that our transition matrices (again, transition matrices, not transition rate matrices: no transition rate matrices are returned for OT or OncoBN), as for OT, are really an abuse of the untimed oncogenetic model.

When using OncoSimulR to represent OncoBN models, there is nothing new. If OncoBN was fitted specifying “CBN”, we use ANDs, if it used “DBN” we use ORs when computing fitness.

5 MHN

MHN has been described in Schill, R., Solbrig, S., Wettig, T., & Spang, R. (2020). Modelling cancer progression using Mutual Hazard Networks. Bioinformatics, 36(1), 241–249. <http://dx.doi.org/10.1093/bioinformatics/btz513>.

We cannot use OncoSimulR as for the rest of the modes, because the MHN model is rather peculiar if taken at face value as an evolutionary model (see Diaz-Colunga, J., & Diaz-Uriarte, R (2021). Conditional prediction of consecutive tumor evolution using cancer progression models: What genotype comes next? PLOS Computational Biology, 17(12), 1009055. <http://dx.doi.org/10.1371/journal.pcbi.1009055>; in particular, see section 1.7 of the Supporting Information: <https://doi.org/10.1371/journal.pcbi.1009055.s001>).

To express MHN in terms of fitness of genotypes, we would need to express it as a model where order of acquisition of mutations matters. This is possible with OncoSimulR⁶, but it does not provide any additional intuition, and can lead to a huge number of fitnesses for a genotype (a genotype with k mutated loci could possibly have $k!$ different fitnesses, one for each of its $k!$ different ways of mutation its k loci).

6 Benefits of this exercise with OncoSimulR

- We make the fitness model explicit.
- We can double check the code in `evamtools` for obtaining fitness graphs and transition probabilities as some critical computations are being done with very different code.

7 License and copyright

This work is Copyright, ©, 2021, Ramon Diaz-Uriarte.

⁶We would need to use “order effects” for the fitness specification. See the vignette for OncoSimulR https://rdiaz02.github.io/OncoSimul/OncoSimulR.html#36_Order_effects, and the help for function `allFitnessEffects`.
